Nonbleed controllers use air only when the branch line pressure is being increased. The air pressure is regulated by a system of valves (Figure 78-9), which eliminates the constant bleeding characteristic of the bleed-type unit. Valves C and D are controlled by the action of the bellows (A) resulting from the changes in room temperature. Although the exhaust is a bleeding action, it is relatively small and occurs only on a pressure increase.

Controlled devices, operators or actuators, are mostly pneumatic damper motors or valves. The principle of operation is the same for both. Figure 78-10 is a diagram of a typical motor. The movement of the bellows as the branch line changes activates the lever arm or valve stem. The spring exerts an opposing force so that a balanced, controlled position can be stabilized. The motor arm L can be linked to a number of functions.

Figure 78-10 Pneumatic actuator with normally open damper.

Figure 78-11 shows a pictorial review of some of the functions in a pneumatic control system. There is always some crossover between the air devices and the electrical system. The device most widely used is the pneumatic/electric relay.

TECH TIP

Unlike electronic and electrical control systems, pneumatic systems do not require any energy when they are in a "hold position." Some electrical and electronic devices consume power even when they are off. This power consumption is referred to as the background power. Although the background power for any single device can be very small, the total power consumed by a large building's control system can be significant. The federal government feels that background power consumption has become so large nationally that the EPA has established guidelines for manufacturers regarding background power consumption. Because pneumatic systems do not have any background power, they are exempt from these regulations.

78.5 ELECTRONIC CONTROL SYSTEMS

Electronic control may also be used effectively for central station equipment. Due to a number of advantages, it is rapidly gaining in popularity. There are no moving parts, the response is fast, and the regulatory element can easily be a reasonable distance from the sensing element. This will allow for adjustments to be made at a central location. There are also cleaner conditions at a central location than at the location of the sensing element.

Only simple low-voltage connections are needed between the sensing element and the electric circuit. Flexibility is important since electronic circuits can be combined with both electric and pneumatic circuits to provide results that could not usually be achieved separately. Electronic circuits can coordinate temperature changes from several sources, such as room, outdoor air, and fan discharge air, and program action accordingly.

Electronic controls are based on the principle of the Wheatstone bridge (Figure 78-12), which is composed of two sets of series resistors (R_1 and R_2 , R_3 and R_4), connected in parallel across a dc voltage source. A galvanometer G (a sensitive indicator of electrical current) is connected across the parallel branches at junctions C and D between the series resistors. If switch S is closed, voltage E (dc battery) energizes both branches. If the potential at C equals the potential at D, the net potential difference is zero. When this condition exists, the bridge is in balance.

If the resistance of any one leg is changed, the galvanometer will register a flow of current. The bridge is now unbalanced. If that resistance is changed as a result of a temperature reaction, we now have an electronic method of measuring current in relation to temperature change. With a few changes we can create an electronic

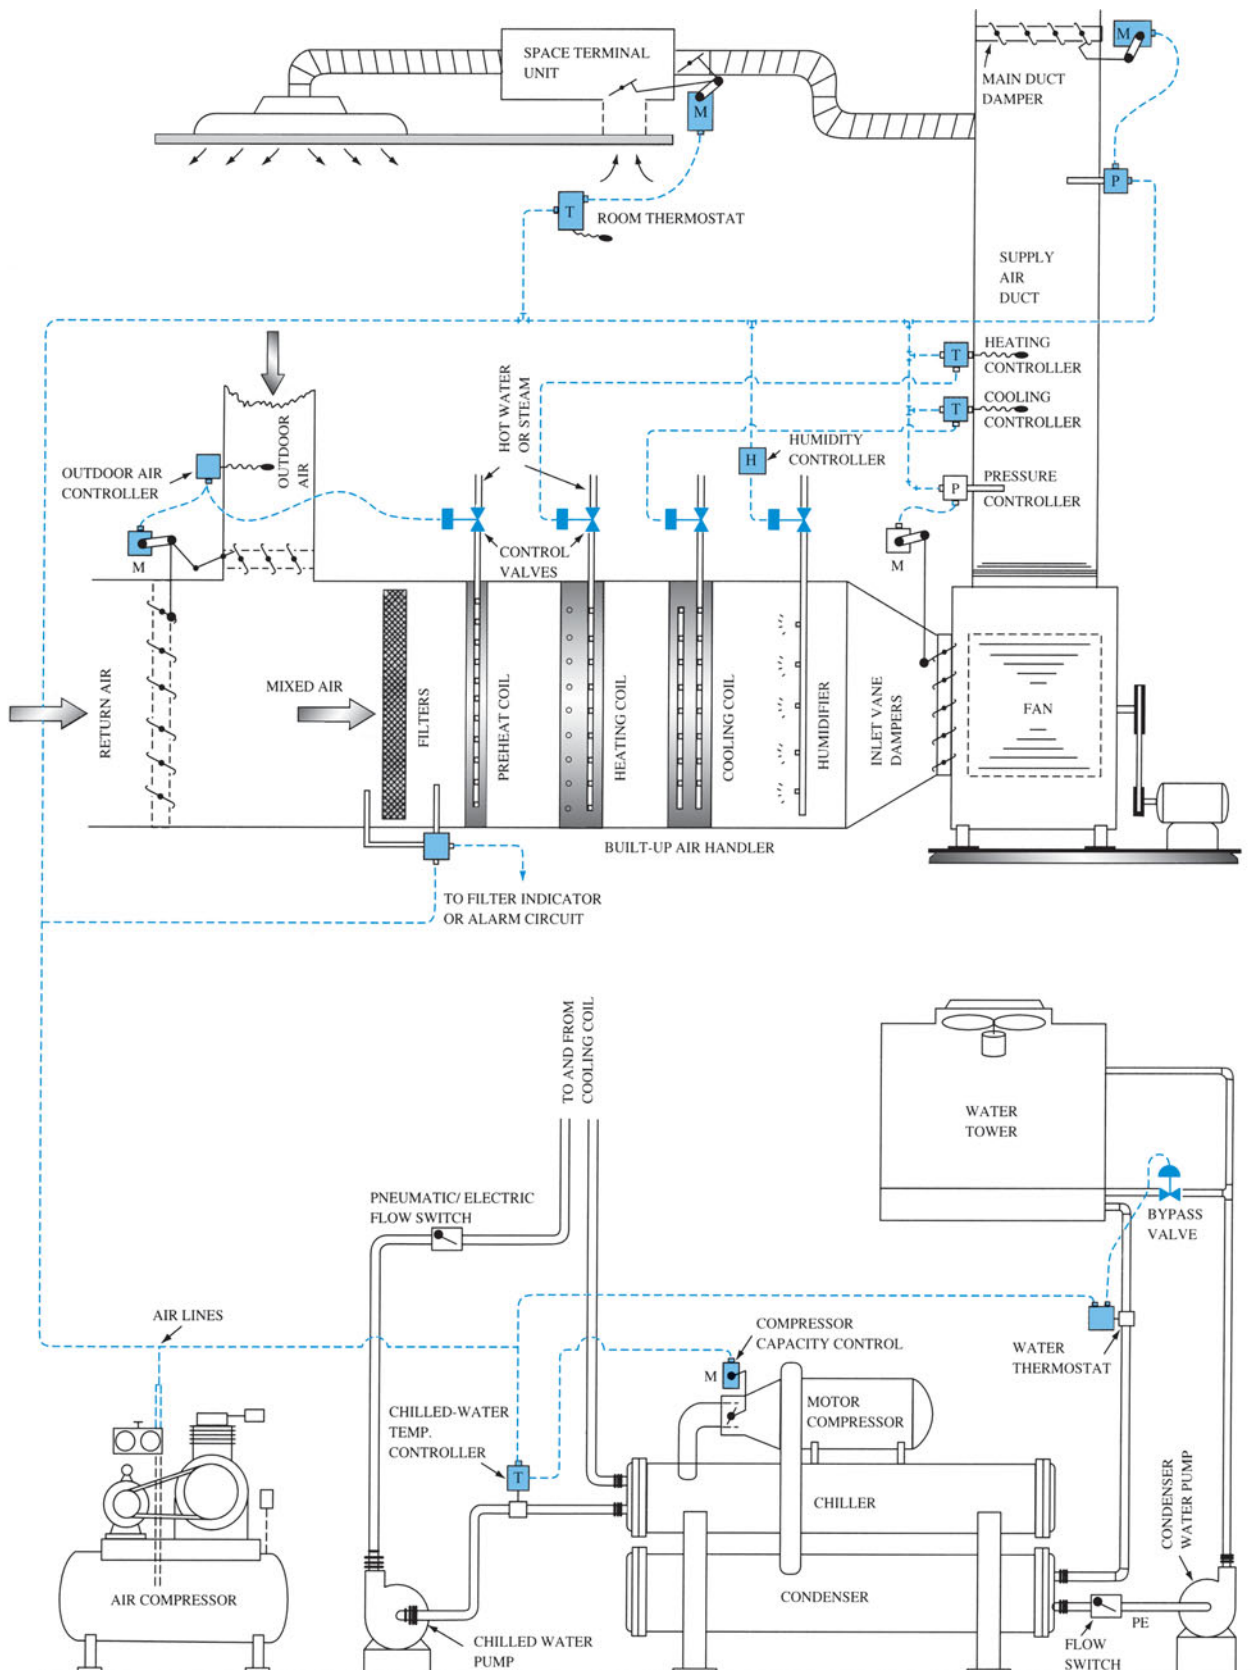

Figure 78-11 System diagram for a central station installation showing pneumatic controls.

Figure 78-12 Wheatstone bridge circuit.

main circuit, such as in Figure 78-13. A 15 V AC circuit replaces the DC battery. The galvanometer is replaced by a voltage amplifier and phase discriminator switching relay. Resistor R_2 is replaced by sensing element T of an electronic controller.

The purpose of the voltage amplifier is to take the small voltage from the bridge and increase its magnitude by stage amplification to do the work. Phase discrimination means determining the sensor action. In an electric bimetal thermostat, the mechanical movement is directly related to the temperature changes; however, the electronic sensing element is a nonmoving part and the phase discriminator determines whether the signal will indicate a rise or fall in temperature. The relay then operates the final element action. Phase discrimination can be two position or, with certain modifications, can be converted to a modular system.

The crossover point from the electronic to electric occurs at the output of the amplifier and relay signal. The motor that it operates is a conventional ON/OFF motor or a proportional (modulating) electric motorized valve or damper actuator.

Electronic temperature-sensing elements are room thermostats, outdoor thermostats, insertion thermostats for ducts, or insertion thermostats for liquids. The typical room thermostat is a coil of wire wound on a bobbin. The resistance of the wire varies directly with the temperature changes.

A sensor is any device that converts a nonelectrical impulse such as sound, heat, light, or pressure into an electrical signal. Sensors have been developed to provide the necessary input for controlling the pressure in a duct or the

relative humidity in a conditioned area. The sensor provides an input to a solid-state controller. The logic in the controller sends an output to some mechanical device to produce the required action.

For example, to control humidity, a pair of electronic sensors read wet- and dry-bulb temperatures. The logic in the controller converts these readings to a relative humidity value. Based on the limits set up, the connected mechanical device is programmed to add or deduct moisture from the air to meet the requirements. The use of electronic equipment makes possible more accurate control of the space conditions than can be accomplished by pneumatic or electromechanical control equipment.

SERVICE TIP

Make sure you follow the manufacturer's procedures when replacing electronic sensors, because some can be damaged by improper handling. Because they may be easily damaged, some supply houses will not allow electronic sensors to be returned once they are removed from their packaging. Make sure you are ready to use the sensor right away before you open the package.

78.6 PACKAGED AIR-HANDLER CONTROL SYSTEM

Packaged air handlers can be factory assembled as one unit or field installed in multiple configurations and modules. Field installation of multiple packaged modules allows for the best match of components for a specific application. Once installed, the packaged air handler will have some type of control panel. Controllers are typically configured to accept hundreds of configuration settings and setpoints. A control module contains the software and microprocessor that control the operation of the unit (Figure 78-14). The module will receive input from all of the different sensors located throughout the air handler that measure air temperature, quality, and condition (Figure 78-15). It will then

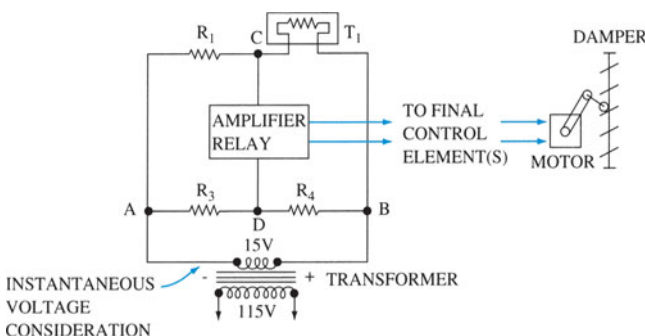

Figure 78-13 Electronic main bridge circuit.

Figure 78-14 Air handler control module.

Figure 78-15 Inputs and outputs for temperature, indoor air quality, humidity, and smoke.

Figure 78-16 Typical air-handler actuator and sensor installation locations.

regulate the supply fan, mixing dampers, and heating and cooling coils as necessary to achieve the programmed condition setpoints.

SERVICE TIP

Most control panels will have a display for fault codes. When troubleshooting a unit, always check this first. The manufacturer's literature will identify the fault code so that you can immediately begin correcting the problem.

78.7 CONSTANT-AIR-VOLUME CONTROL SYSTEM

Depending on the system configuration, there will be a variety of temperature, condition, and alarm sensors. These include supply-air temperature, low-temperature thermostat, filter differential pressure switch, mixed air temperature,

airflow switch, and preheat temperature. Typical sensor locations are shown on the air handler in Figure 78-16.

These measured input signals are compared to the setpoints programmed into the controller, and the appropriate actions will be taken on the supply-fan relay (start/stop), mixed-air damper actuator, heating coil valve/electric heater, cooling coil control valve or direct expansion control (depending on the system), and the exhaust damper position.

Temperature Input Signals

A number of the input signals are temperature measurements. The supply-air temperature sensor is installed on the discharge side of the air handler for measuring the supply-air temperature for the conditioned space (Figure 78-17). The low-temperature thermostat measures the temperature of the air as it passes across the cooling coil. The thermostat consists of a long length of serpentine capillary tubing that is installed on the inlet side of the coil. It will be set to shut down the fan and set off an alarm if the air

Figure 78-17 Temperature sensor located in the supply-air plenum.

temperature drops below 35°F. This is essentially a backup for the preheater, which receives its signal from the preheat temperature sensor. This preheat sensor is also serpentine capillary tubing, but it is located on the outlet of the preheater coil rather than at the inlet (Figure 78-18).

The mixed-air temperature sensor is mounted in the mixing box and has direct input for the spring-return damper actuator (Figure 78-19). The damper control assembly will modulate the damper position through a linkage (Figure 78-20), based upon the input signal from the mixed-air sensor.

SERVICE TIP

A malfunctioning sensor can sometimes be difficult to diagnose, but by logically working through a step-by-step sequence of operation, the different possible problems can be eliminated one by one. More difficult to troubleshoot is an improperly placed sensor. Always follow the manufacturer's recommendations when reinstalling sensors.

Figure 78-18 Capillary tube routing for low-temperature thermostat on heating application only.

Figure 78-19 Spring-return damper actuator.

Figure 78-20 Assembled actuator and linkage.

Airflow Input Signals

There are also airflow input signals. The airflow switch consists of a probe mounted in the fan discharge duct. This snap action switch verifies that the fan is either on or off. The filter status switch is set to alarm as the differential pressure increases once the filters become dirty (Figure 78-21).

78.8 VARIABLE-AIR-VOLUME CONTROL SYSTEM

This system differs from the constant-volume/variable-temperature system since basically it maintains a nearly constant air temperature but matches the load by changing the air volume. This system became popular when attention was given to conserving energy without decreasing the comfort level during partial-load conditions.

One of the features of these systems is the use of a variable-frequency fan-speed controller that is applied to the air-handler fan (Figure 78-22). This electrical device, along

Figure 78-21 Filter status switch.

with the necessary sensors, controls the speed of the central fan to match the total air volume required by the individual zone terminal units. As an example, a static pressure sensor can be installed in the airflow to reduce the speed of the fan as the air supply demand decreases and the static air pressure rises (Figure 78-23). Since the power required for driving the fan is proportional to the cube root of the fan speed, tremendous power savings can result from slowing down the fan when the extra air is not needed.

Many of the input signals and controls are similar to the constant-air-volume system, with some exceptions. The fan motor is a variable-frequency drive unit (VFD). Because of this, a static pressure transducer and probe are installed rather than an airflow switch. The fan speed can be varied according to the static pressure in the system to supply more or less air as the system requires. There is also a temperature sensor located in the return-air supply.

Also included in a VAV system is a high-pressure switch. This switch will shut down the fan if the duct pressure

Figure 78-23 Duct static pressure probe.

exceeds the setpoint. Additional fan shutdowns are the low-temperature thermostat and the fire shutdown relay.

78.9 AIR-QUALITY AND AIR-CONDITION SENSORS

Sensors can be used to measure the quality and condition of the air, such as CO₂ levels, enthalpy, and humidity throughout different locations within the air-distribution system. They can be used for simple data acquisition where the measured output—as an example, the CO₂ level—is read from a display. A more significant advantage to sensors is that many electronic control systems will use their output to automatically control actions such as damper positioning and fan modulation.

Air Quality

CO₂ levels are monitored in the conditioned air space and can also be monitored in the return-air duct. These sensors use infrared technology with a range of 0–2,000 ppm. The amount of outside air admitted will be adjusted to control the setpoint level.

Differential Enthalpy Control

Two individual sensors are used, with one sensing the outside air enthalpy and the other sensing the return air enthalpy (Figure 78-24). This is used for the economizer

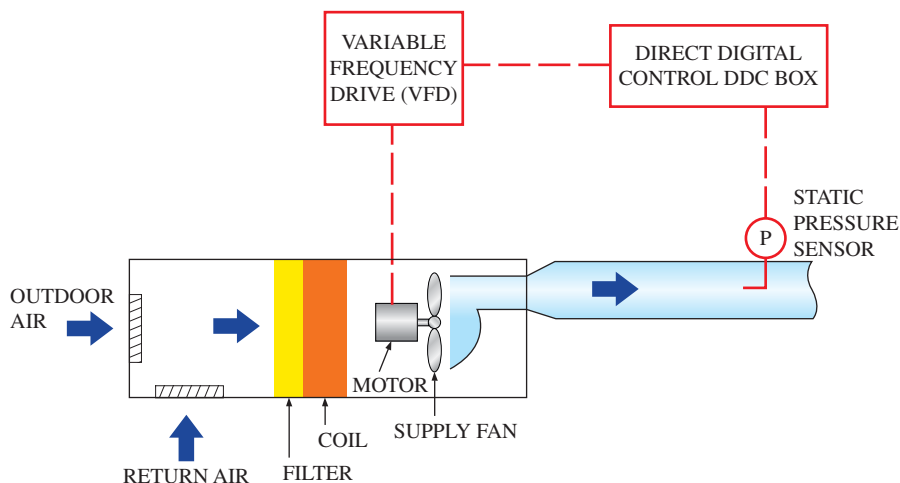

Figure 78-22 Supply-fan control.

Figure 78-24 Differential enthalpy control sensor.

section. The airstream with the lowest enthalpy will be directed by dampers through the economizer section.

Space Humidity

The humidity level is monitored in the conditioned space and is mounted in a location that is representative of the entire zone. This sensor can be used for adjusting the cooling coil face and bypass dampers to allow for sufficient cooling of the air for dehumidification.

78.10 DIRECT DIGITAL CONTROL SYSTEMS

In a direct digital control (DDC) system, the computer acts as the primary control for all HVACR functions. Valves, dampers, fan speeds, and so on are all controlled by the computer without the use of conventional control devices such as thermostats, humidistats, or timers.

The computer directly senses the building environmental conditions and, based on a user-defined programmed set of instructions, initiates the proper control actions in the HVACR system. Direct digital control of HVACR components gives more accurate control and greater flexibility than other commonly used mechanical and electrical control devices. It also has the capability of coordinating inputs from a number of sensing devices and arriving at an output that takes into consideration numerous influencing factors. The following are some examples of the capabilities of the DDC control systems:

- The DDC system can control a VAV terminal box to discharge the proper air supply based on a variety of inputs, such as dry-bulb temperature, relative humidity, and mean radiant temperature. In this way, considering the total environmental conditions, a greater feeling of comfort is produced for the occupants in the space. Figure 78-25 shows a computer-generated control screen for an exhaust-air handler.
- In a central station system with a large supply fan, the microprocessor can regulate the speed of the fan to

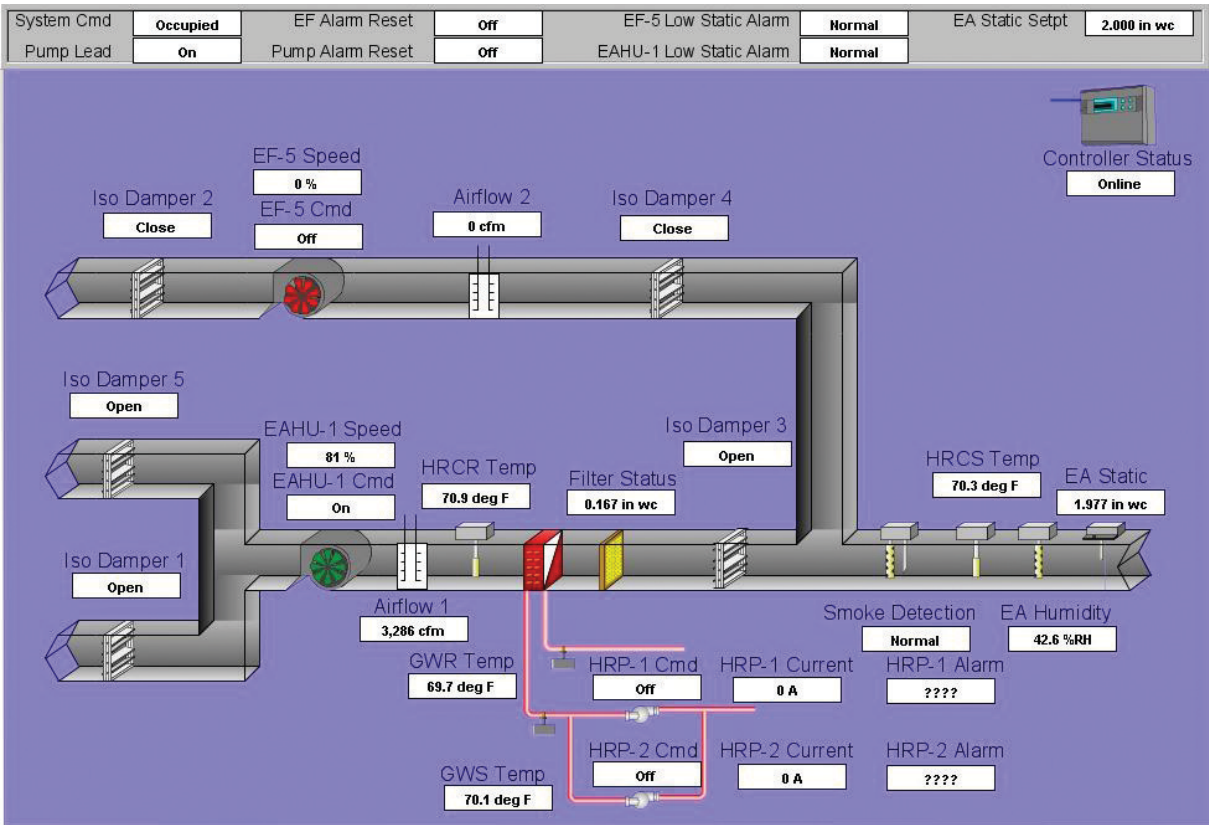

Figure 78-25 Computer-generated control screen for an AHU. (Courtesy of the Jackson Laboratory)

produce the required airflow using a minimum amount of power.

- Computers are currently used to turn on chillers and boilers at an optimum time to recover from a period when the building is unconditioned. Figure 78-26 shows a computer-generated control screen for a bank of chillers, the chilled water pumps, and the operating temperatures and pressures for the system.
- Control from a remote location. As an example, a building in California could be monitored and controlled from a location in Georgia.

These systems operate with a central stand-alone controller connected to a series of remote-control units.

The individual remote-control units are located in the building near the equipment being controlled. These units have a series of input and output wiring connections that go to sensors and controls on the HVACR system that permit control of the operations of the system. Both the input and output functions are of two types: analog and digital. The analog functions supply or deliver modulated information. For example, an analog temperature sensor may be capable of reading temperatures between 0°F and 100°F. This input could be converted by the computer to produce an analog output signal to control a damper to any position between fully open and fully closed.

The digital function is a binary, or two-position, function. For an input, the signal could monitor whether a switch

is open or closed. For output, the binary signal could position the switch in either an ON or OFF position.

The DDC systems are often called energy-management systems since one of their main functions, and usually justification for their adoption, is saving energy. Special provision has been made in the selection of sensors to make possible continuous monitoring of the energy usage. The control system is set up to energize loads only when necessary and to use such features as free cooling (economizer operation) whenever possible.

The control center collects key operating data from the HVACR system and incorporates remote-control devices to supervise the system's operation. The elaborateness of the data center is related to the type and size of the system and to economic considerations. Some control centers have continuous scanners with alarm indicators to monitor refrigeration machines, oil and refrigerant pressures, chilled-water temperatures, air filter conditions, low water conditions in the boiler, and conventional space temperature and humidity conditions in each zone.

An example of a computer-generated control screen for the heat-reclaim section of an air handler is shown in Figure 78-27. This includes fan operation, all the damper positions, and the valve positions for coil control of glycol, steam, and chilled water. The screen shown in Figure 78-28 controls the cooling water tower loop for the chillers.

Screens are designed to help the operator visualize the process with a graphical display that best represents the

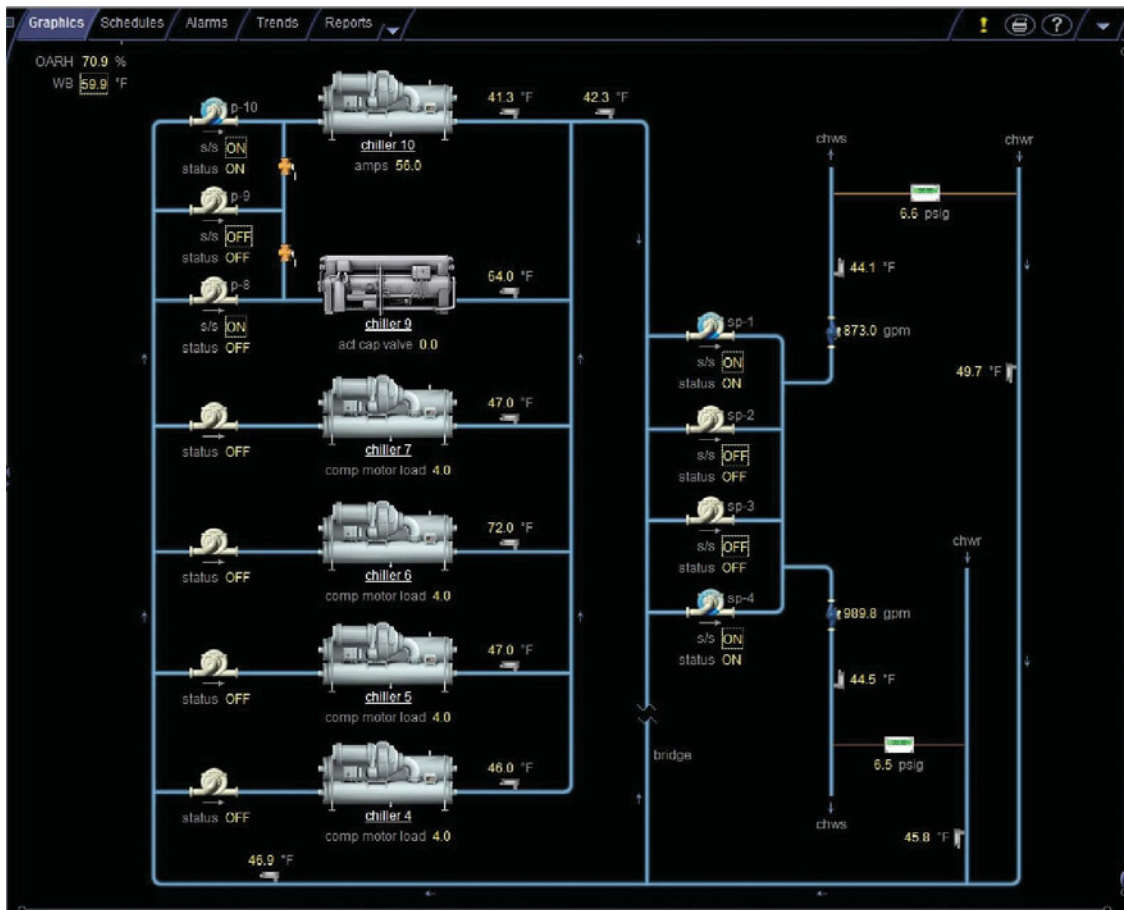

Figure 78-26 Computer-generated control screen for a bank of chillers and chilled-water pumps. (Courtesy of the Jackson Laboratory)

system, as shown in Figure 78-29. This screen has state-of-the-art graphics that represent coils and valves and an air flow sequence that can be easily interpreted. The detail is such that even the steam humidifiers and sensing probes are shown.

Vibration Monitoring

Vibration-monitoring systems are part of what is called “predictive” maintenance. Rotating equipment such as fans can be continuously monitored for excessive vibration levels. To reduce vibration, large fans may be mounted on resilient mounts, such as springs (Figure 78-30). Even so, over time the fan bearings will wear and vibration levels will

Figure 78-30 Large fan mounted on springs to reduce the effects from vibration.

increase. Vibration can also result from worn belts, loose pulleys, and loose foundation bolts.

For continuous monitoring, sensors need to be installed on the equipment (Figure 78-31). These vibration sensors will measure the “amplitude” (acceleration) of the vibration and trigger an alarm if levels exceed set limits. This vibration signature can be tracked over time to help determine when a piece of equipment may need to have bearings replaced or be in need of other types of overhaul. The life of

(a)

Figure 78-31 (a) Rotating equipment such as fans can be fitted with vibration sensors; (b) (see next page) vibration sensor wiring.

Figure 78-31 (Continued)

the equipment can be predicted in a sense, so that components are not replaced prematurely. Continuously monitoring the equipment also reduces the chance that the unit will fail unexpectedly and without warning.

The frequency of the signature helps to determine the cause of the vibration. Different problems occur at different frequencies. Vibration from a bad bearing will provide a different frequency signature as compared to an unbalanced fan blade or loose hold-down bolt. An example of a computer-generated screen showing the frequency and amplitude signature for a fan motor is shown in Figure 78-32.

UNIT 78—SUMMARY

Many control systems today are electronic; however, a combination of electric, electronic, and pneumatic controls can be used on large commercial systems.

Figure 78-32 Continuously monitored vibration signature for a motor showing the amplitude and frequency of vibration. (Courtesy of the Jackson Laboratory)

WORK ORDERS

Service Ticket 7801

Customer Complaint: Compressors Run Constantly Even When the Outside Air Is Cool Enough for System to Be in Economizer Mode

Equipment Type: Light Commercial Air Handler with DX Coil and Economizer Package

The technician operates the system while doing a visual check. Even though the outside temperature is low enough for economizer operation, the compressor is not turning off and the outside air dampers (OA) are not opening. After examining the operation sequence and electrical diagram, the technician suspects a faulty economizer control thermostat. After testing, the technician proves that the control is defective. The technician replaces and sets the thermostat. The technician then tests the system by placing the sensing bulb in ice water. The compressor cycles off and the OA damper opens per the manufacturer's specifications. The system is now operating as designed.

Service Ticket 7802

Customer Complaint: System Has Shut Down Completely

Equipment Type: 100-Ton Central Station Unit with Pneumatic Control

The technician talks to the maintenance department and realizes there must be a complete shutdown of either the electrical power or the control system. The technician checks the electrical power and all the systems are energized. The technician checks the control system and finds the control system air compressor is not running and the pressure is down to zero. Troubleshooting the air compressor reveals a bad pressure controller that would not allow the control air compressor to operate. After replacing the switch, the technician turns the compressor on and the system operates as designed.

Service Ticket 7803

Customer Complaint: The Third Floor of a Multistory Building Has Reported a "Cold Call"

Equipment Type: Air Handler with Heating and Cooling Operated from a Large Central Station Unit

The technician is taken to the area by a maintenance technician. The AHU is located in a third-floor fan room. The technician connects the laptop computer to the

ports furnished in the DDS controller located on the unit. The technician tries to cycle the unit from cool to heat and diagnoses a bad controller that will not cycle the damper, bring on the heating fan, or open the HW control valve. The technician replaces the DDS controller inside the control panel, and the system now heats and cools as designed.

UNIT 78—REVIEW QUESTIONS

1. What is the function of a low-temperature thermostat on a packaged air handler?
2. What is the function of an airflow switch on a packaged air handler?
3. What input signal would control the speed of a variable-frequency drive supply fan?
4. What is the purpose of a high-pressure switch in a packaged air handler?
5. What will an air-quality sensor typically measure?
6. What is the purpose of a differential enthalpy sensor?
7. How does a refrigeration air dryer operate?
8. How would a humidity control operate?
9. What is an important consideration to take into account when replacing sensors?
10. Why are direct digital control (DDC) systems sometimes referred to as energy-management systems?
11. What could cause vibration in a large air-handler fan?
12. What do vibration monitors specifically measure?
13. What types of control valves are used for heating and cooling coils?
14. What can happen if the pressure drop through a heating or cooling coil control valve is excessive?
15. List some of the advantages of pneumatic control systems.
16. What is background power?
17. What are some of the advantages of electronic control systems?
18. List some electronic temperature-sensing elements.
19. What acts as the primary control for all HVACR functions in a DDC system?
20. What is a sensor?

UNIT 79

Chilled Water Systems

OBJECTIVES

After completing this unit, you will be able to:

1. describe the difference between a flooded and a dry (direct expansion) type chiller.
2. explain why low-pressure chillers need purge recovery.
3. explain why some chillers are better suited for air-cooled condensers while others operate with water-cooled condensers.
4. list the different types of compressor arrangements found on chillers.
5. describe the function of a chiller economizer.
6. describe the operation for an oil-return system for a chiller.
7. transfer refrigerant to and from a chiller.
8. explain how an absorption chiller operates.

79.1 INTRODUCTION

In a large multistory building or complex, it is impractical to deliver refrigerant long distances from a central air-conditioning compressor and condensing unit. Excessive energy would be required for the compressor to deliver the refrigerant to different air handlers located on different levels of the building. Any leaks in the system could lead to a substantial loss of refrigerant before they could be detected.

The more common way to deliver refrigerant to individual air handlers is to use a secondary refrigerant such as chilled water. The chilled water is cooled in a central station chiller by a primary refrigerant. The chilled water is then delivered throughout the building to individual air handlers by circulating pumps (Figure 79-1). Any leaks in this system are easily detected. The primary refrigerant does not leave the central air-conditioning unit.

79.2 FLOODED AND DRY-TYPE WATER CHILLERS

The water in a chiller is cooled to approximately 43–45°F. The chilled-water pump circulates the chilled-water supply (CHWS) to the cooling coil in the air handler. The chilled-water loop will have an expansion tank and fill connections for makeup water, and it will also have air vents, balancing valves, and cooling coil flow controls, as shown in Figure 79-2. The heat absorbed from the air by the cooling coil warms the water about 10°F at full load, with a chilled-water return (CHWR) temperature of 53–55°F.

The cooler section is the evaporator where the primary refrigerant changes state and absorbs heat from the chilled water. The cooler section, often referred to as the chiller, is often cylindrical in shape and of the shell-and-tube design. A “dry” direct expansion (DX) cooler will

(a)

(b)

Figure 79-1 (a) Chilled-water cooling loop from central unit to multiple zones; (b) glycol and chilled-water piping connections to the air handler.

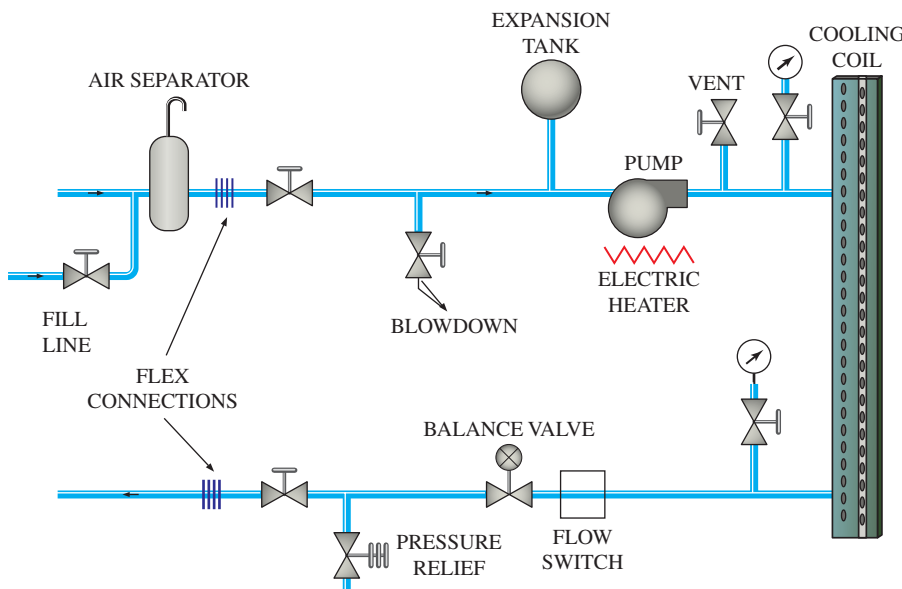

Figure 79-2 Chilled-water cooling loop for cooling coil.

Figure 79-3 Centrifugal compressor chiller.

circulate the refrigerant through the inside of the tubes, and the chilled water will surround the tubes. For larger tonnage units, flooded coolers are more commonly used. In a flooded cooler, the refrigerant surrounds the tubes and the chilled water is circulated through the inside of the tubes. Flooded coolers have greater cooling capacities, but they require more refrigerant and have a greater potential for freeze-up as compared to DX coolers. Figure 79-3 shows a centrifugal compressor chiller with a flooded cooler and subcooler section.

79.3 LOW-PRESSURE CHILLERS

The chilled-water temperature for an air-conditioning system should not fall much below 40°F. A temperature sensor located in the chilled-water circuit provides an input signal to the compressor operation and capacity controls. Many systems will automatically shut down if the chilled-water temperature drops to 35°F. Low-pressure refrigerants are those that have boiling points of 50°F or above. This high boiling temperature would not be suitable for

low-temperature applications; however, it is suitable for chiller applications. To achieve the desired refrigerant temperature, many chillers operate with suction pressures below atmospheric pressure.

For large air-conditioning loads, a considerable amount of refrigerant must be circulated by the compressor. Centrifugal compressors are able to pump large volumes of refrigerant as compared to reciprocating compressors. However, they do not develop the high-side discharge pressures of a reciprocating compressor. Since low-pressure refrigerants do not require such high discharge pressures, they are ideally suited for centrifugal chiller applications.

79.4 PURGE RECOVERY UNITS

A low-pressure chiller will operate with a negative suction pressure that is below atmospheric. Any leaks in the system will draw in air. This air typically collects in the top section of the condenser. The air will increase the discharge pressure of the unit and lead to higher compressor power consumption. The air will also contain water that will oxidize the oil in the system and lead to the formation of sludge and acids. Chillers of this type generally have some type of purge recovery unit (Figure 79-4). This unit will purge the air from the top of the condenser and recover the refrigerant on a continuous basis while the chiller is running.

79.5 LEAK TESTING LOW-PRESSURE CHILLERS

Leak testing a low-pressure chiller is difficult because air will be leaking in rather than refrigerant leaking out. One way to check for refrigerant leaks in a low-pressure chiller is to raise the temperature of the chilled water. The unit is shut down and the chilled water is heated and circulated through the cooler. This will raise the pressure in the unit above atmospheric pressure so that a conventional leak detector can be used to find any refrigerant leaks.

Figure 79-4 Purge recovery unit.

Figure 79-5 Centrifugal compressor suction-side rupture disk.

CAUTION

Never allow a low-pressure chiller to reach or exceed the rupture disk setting when testing for leaks. The rupture disk setting for low-pressure chillers is normally set at 15 psig, but it is advisable not to exceed 10 psig. If this happens, then the chiller rupture disk will release and all of the refrigerant in the unit will be lost (Figure 79-5).

79.6 RECIPROCATING COMPRESSOR CHILLERS

Reciprocating compressors have been commonly used with small to moderate size chillers. This has been changing, since many newer units are now utilizing more efficient scroll compressors. The total refrigerant capacity for reciprocating compressors is somewhat limited, so large chillers will use centrifugal and screw-type compressors.

Air-Cooled Condensers

Starting at the lower capacities, packaged water chillers use one or more reciprocating compressors. Figure 79-6 shows an example of a small air-cooled chiller in the 30-ton range. This type of unit would be mounted directly outside or on a rooftop with supply and return connections for the chilled water piped into the building. For head (discharge) pressure control, the condenser fan control receives input from a pressure transducer (Figure 79-7). The fans are maintained at the lowest condensing pressure and temperature possible to maintain the highest unit efficiency.

The coolers for this type of unit are typically the “dry” DX type. Refrigerant flows through the tubes and will generally make two passes for standard operation, which provides a counterflow arrangement, opposite to the typical chilled-water flow pattern. The cooler shell is suspended beneath the condenser coil and fan section. The cooler shell (evaporator) must be protected from freezing. Electric heating elements are wrapped around the shell and then covered with a thick layer of insulation. Some manufacturers also add a final protective metal jacket that doubles as a good vapor barrier.

The larger package chillers with reciprocating compressors can be air cooled or water cooled and range upward from 40 to 200 tons. The cooler and compressor can be located indoors and the air-cooled condenser located on the rooftop, as shown in Figure 79-8a, or outside the building, as shown in Figure 79-8b. Another option is to locate a water-cooled condenser alongside the compressor. If a ready supply of water for the condenser is not available, then a cooling tower will be required. The cooler shell and suction lines must be properly insulated to prevent sweating. This is done at the factory with a layer of closed-cell foam insulation prior to painting.

Water-Cooled Condensers

Most water-cooled condensers are shell-and-tube construction. Water flows through the tubes, and refrigerant vapor fills the shell. The refrigerant vapor condenses to a liquid as heat is transferred from the refrigerant to the water. The liquid collects in the bottom, where it is subcooled an additional 10–15°F for greater cooling capacity. In the water circuit, the coldest condenser water enters the lower part of the shell and circulates through the tubes. The water will make two or three passes through the shell before it is discharged. This is arranged by circuit baffles in the condenser heads. The higher the number of passes, the greater the pressure drop and pressure required to produce the required condenser cooling-water flow rate. Condenser capacity is normally based on 85°F entering water temperature. There is normally a 10°F rise between the exiting and entering water temperatures.

TECH TIP

A special seawater condenser is used for marine duty where saltwater is the cooling medium. These tubes are made of cupronickel steel to withstand the salt corrosion effects.

Figure 79-6 Package chiller with reciprocating compressor.

Figure 79-7 Control sensor: pressure transducer.

79.7 RECIPROCATING COMPRESSOR CAPACITY CONTROL

The larger tonnage units will have multiple compressors that permit close control of capacity. They are also generally equipped with cylinder unloaders and hot-gas bypass. As an example, consider a two-compressor unit with one compressor set as the lead and the other as the lag. During peak periods, both compressors would be running fully loaded. In the early evening as the load begins to decrease, the chilled-water temperature will begin to drop. This will signal the lag compressor to begin unloading cylinders sequentially and run at a reduced capacity. At some point the load will decrease to the point that the lag compressor stops. If the load continues to decrease, the lead compressor will begin unloading cylinders. Eventually, when the lead compressor is fully unloaded, the hot-gas bypass will open.

79.8 SCROLL COMPRESSOR CHILLERS

In addition to reciprocating compressors, the scroll-type compressor is being utilized increasingly in packaged chillers. These compressors use a pair of mating scroll-shaped

Figure 79-8 (a) Air-cooled condenser installation with a package chiller; (b) remote air-cooled condenser.

surfaces to compress the refrigerant with pure rotary motion, as shown in the cutaway diagram in Figure 79-9. The individual scroll compressors are very efficient and are used in sizes from 5 to 20 tons. Since they have limited capacity control, they are usually used in multiples of two, three, or four compressors that cycle on and off dependent on the load demand.

79.9 CENTRIFUGAL COMPRESSOR CHILLERS

For very large installations, the industry offers a range of hermetic centrifugal compressor water chillers of up to 2,000 tons in a single assembly. Very large buildings or complexes such as college and school campuses, sports arenas, airports, and high-rise office buildings may use more than one chiller to meet their cooling needs.

Hermetic centrifugal compressors (Figure 79-10) vary in design and refrigerant type. This unit has a hermetically sealed motor that will drive the compressor through a set of transmission-speed-increasing gears. The compressor speed is typically much higher than the motor speed. The refrigerant vapor is drawn from the cooler into the suction eye of the rotating impeller (Figure 79-11). The pressure of the refrigerant is increased as it passes through the discharge of the spiral compressor casing (volute) and into the condenser (Figure 79-12). The high-pressure refrigerant vapor is condensed and passes through a fixed orifice or float chamber to return to the cooler. There is also a much smaller additional cooling circuit fed by expansion valves

Figure 79-9 Cutaway view of a scroll compressor. (Courtesy of Danfoss)

Figure 79-11 Centrifugal compressor impeller.

Figure 79-12 Compressor discharge through casing volute to condenser.

for the oil, hermetic motor, and the variable-frequency drive. The typical configuration is for the compressor, condenser, and cooler to all be located together to circulate the refrigerant a minimal distance.

79.10 CENTRIFUGAL COMPRESSOR STAGING

Single-stage centrifugal compressors will have only one impeller. A two-stage unit will have two impellers. The first impeller will discharge into the suction of the second impeller and then to the condenser. A three-stage unit will have three impellers, and so on. More stages results in higher discharge pressures, which allows for the use of high-pressure refrigerants such as R-134a. Low-pressure chillers operating with low-pressure refrigerants such as R-123 can be simple single-stage units that operate at high speeds in the 10,000 rpm or higher range. Some gear-driven impellers reach speeds of 20,000–25,000 rpm.

Typically, more stages and higher pressures require more power input and the compressor arrangement is somewhat more complex. However, multiple stages generally require lower speeds, which can offset the power requirements. Lower speed units are also less susceptible to the vibration problems that can be encountered with very-high-speed units. High-pressure chillers do not require continuous purge recovery systems.

79.11 CENTRIFUGAL COMPRESSOR DRIVES

The most efficient form of capacity control for a centrifugal compressor is to regulate the speed. At low loads the speed of the unit will be decreased. This requires a variable-speed prime mover. Depending on the location and application for the unit, there are a number of possible choices for prime movers. Variable-frequency drive (VFD) ac motors are becoming more popular. The price for this type of drive has been coming down, and the savings from efficient operation help to defray the initial cost.

Steam turbines provide for very reliable speed control, but a ready supply of steam is required. Gas turbines only need a connection to a natural gas source, which is commonly available in many urban areas. Simple cycle gas turbine efficiency is rather low, however, so this type of system when utilized is better suited to a combined cycle application. In a combined-cycle system, the energy from the heat of the gas turbine exhaust is recovered to generate steam or to augment some other heating requirement.

TECH TIP

Some chiller systems use heat-recovery units to provide hot water for the building. Heat-recovery units pick up waste heat from the condenser to provide “free” hot water.

Diesel engines have much higher efficiencies than gas turbines, but they are not suited for operating at low loads. The newest diesel engines designed to specifically

operate chillers use natural gas or propane as a fuel rather than diesel fuel. These engines are referred to as “spark ignited” diesel engines. Many of the inherent problems encountered from operating a traditional diesel engine at low loads are significantly reduced. If there is ready access to a gas line, this type of prime mover can be a reasonable choice.

79.12 CENTRIFUGAL COMPRESSOR CAPACITY CONTROL

The most efficient method of capacity control is to reduce the compressor speed at low loads. This cannot be the only method because many older centrifugal units are driven by constant-speed AC motors. Variable-speed prime movers may also have limitations in speed reduction and only operate within a specific range. To accommodate this, most centrifugal compressors will have variable inlet guide vanes located at the compressor suction. These vanes will be closed at low load and at compressor start-up, as shown in Figure 79-13a, and open at high load, as shown in Figure 79-13b.

(a)

(b)

Figure 79-13a (a) Inlet guide vanes in the closed position; (b) inlet guide vanes in the open position.

As the load on the centrifugal compressor decreases and the inlet guide vanes begin to close, the pressure in the condenser may become unbalanced. When this occurs, the compressor will surge. To reduce compressor surging at low loads, hot-gas bypass is frequently utilized. A portion of the discharge will be bypassed through a solenoid-operated valve back into the suction side. When the compressor is operating at normal loads, the hot-gas bypass valve should be closed.

79.13 SCREW COMPRESSOR CHILLERS

An important type of packaged water chiller uses the helical rotary compressor (Figure 79-14), commonly known as a screw compressor because of the appearance of the rotors. Screw compressors and their chiller packages were originally developed as effective units for the refrigeration needs of the food and chemical industries. They have been successfully adapted to the needs of the comfort air-conditioning market, with industrial-based technology.

The twin rotor screw compressor, illustrated in Figure 79-15, uses a mating pair of rotors with lobes that rotate

Figure 79-14 Screw compressor, end view.

Figure 79-15 Diagram of the rotors of a screw compressor.

Figure 79-16 Cooling water tower for closed-loop water-cooled condenser.

much like a pair of gears. During rotation, the space or mesh between the lobes first expands to draw in the suction gas. At a point where the interlobe space is at maximum, the lobes seal off the inlet port. As the lobes rotate, the interlobe space becomes smaller as the gas is carried to the discharge end of the compressor. The refrigerant gas is internally compressed by this positive-displacement compressor until the rotors uncover the discharge port, where the compressed gas is discharged from the compressor.

Screw compressors are used because of their high capacity for a small unit and their continuously variable (stepless) capacity control, typically modulating from 100 to 10 percent of full capacity. Being positive displacement, screw compressors have piping flexibility to accommodate remotely located condensers and can be used with high-pressure refrigerants. They can operate with both water- and air-cooled condensers. Cooling water towers may be used for closed-loop water-cooled condensers (Figure 79-16).

Screw compressors come in a variety of configurations, depending on the manufacturer and application. One common type is the horizontal open-drive unit, typically driven at 3,500 rpm by an external motor. Many packaged chiller units use semihermetic construction on the compressor, eliminating the problems of shaft alignment and mechanical shaft seal leakage. Some newer designs utilize three screws. This shortens the overall length and increases the compression efficiency.

79.14 SCREW COMPRESSOR CHILLER OPERATION

The cycle for a screw compressor chiller with a water-cooled condenser is similar to the centrifugal compressor chiller. Figure 79-17 shows a hermetic screw compressor drawing suction from a flooded cooler. The refrigerant vapor is compressed and discharged into the condenser. A float valve will control refrigerant flow and allow for the pressure drop required for the refrigerant to expand in the cooler. A hot-gas bypass solenoid-operated valve is used to recirculate refrigerant at low loads. Also shown are the cooling circuits for the hermetic motor and the

variable-frequency drive. Capacity for this unit is controlled by adjusting the motor speed.

79.15 CHILLER ECONOMIZER OPERATION

Many large commercial centrifugal and screw-type chillers utilize economizer sections. Their purpose is to subcool the liquid refrigerant before it enters the cooler. An economizer section is shown in Figure 79-18. The refrigerant leaving the condenser as a liquid passes through an orifice into the economizer section. The pressure in the economizer is between the condenser and the cooler operating pressures. Due to the drop in pressure in the economizer, some of the liquid refrigerant flashes into a vapor and is returned back to the compressor. This flashing in the economizer subcools the liquid that then passes on to the cooler. Due to this subcooling, less flash gas is produced when the liquid refrigerant passes through the fixed orifice and enters the cooler. This will provide more available liquid refrigerant in the cooler.

The refrigerant that flashes in the economizer is not piped directly back to the compressor suction. Since the economizer is at a higher pressure than the suction pressure, the vapor can enter the compressor at an intermediate point, or in the case of a staged compressor, in a later stage. If no economizer section is used, this vapor will still be formed as flash gas in the cooler but will require more energy to compress it from suction pressure to discharge pressure as compared to compressing the vapor from economizer pressure to discharge pressure.

79.16 CHILLER OIL RETURN

The oil in many large commercial centrifugal and screw-type chillers travels through the system and collects in the bottom of the cooler. The compressor normally draws suction from the top of the cooler to reduce any possibility of a liquid slug. Without some type of oil-return system, the oil will not be able to be reintroduced into the lubrication circuit.

Figure 79-19 illustrates an example of a typical oil-return system for a hermetic screw-type compressor chiller. A metered amount of oil collecting in the bottom of the cooler is allowed to pass to the vaporizer section. Hot gas from the condenser passes through a coil located in the vaporizer. This will vaporize any liquid refrigerant that has been carried over with the oil. The oil then passes from the vaporizer to the oil sump, where an electric heater is utilized to further vaporize any refrigerant liquid entrained in the oil. Mist eliminators are used to remove any entrained oil in the refrigerant vapor before returning to the compressor suction. This reduces the possibility of any oil carryover that would slug the compressor.

79.17 CHILLER REFRIGERANT RECOVERY AND TRANSFER

Periodically, chillers may need to be pumped down for servicing. Unlike some commercial systems that utilize receivers, there is no place to transfer the refrigerant other than an external storage tank. The external storage tank

Figure 79-17 Screw compressor refrigerant flow without economizer.

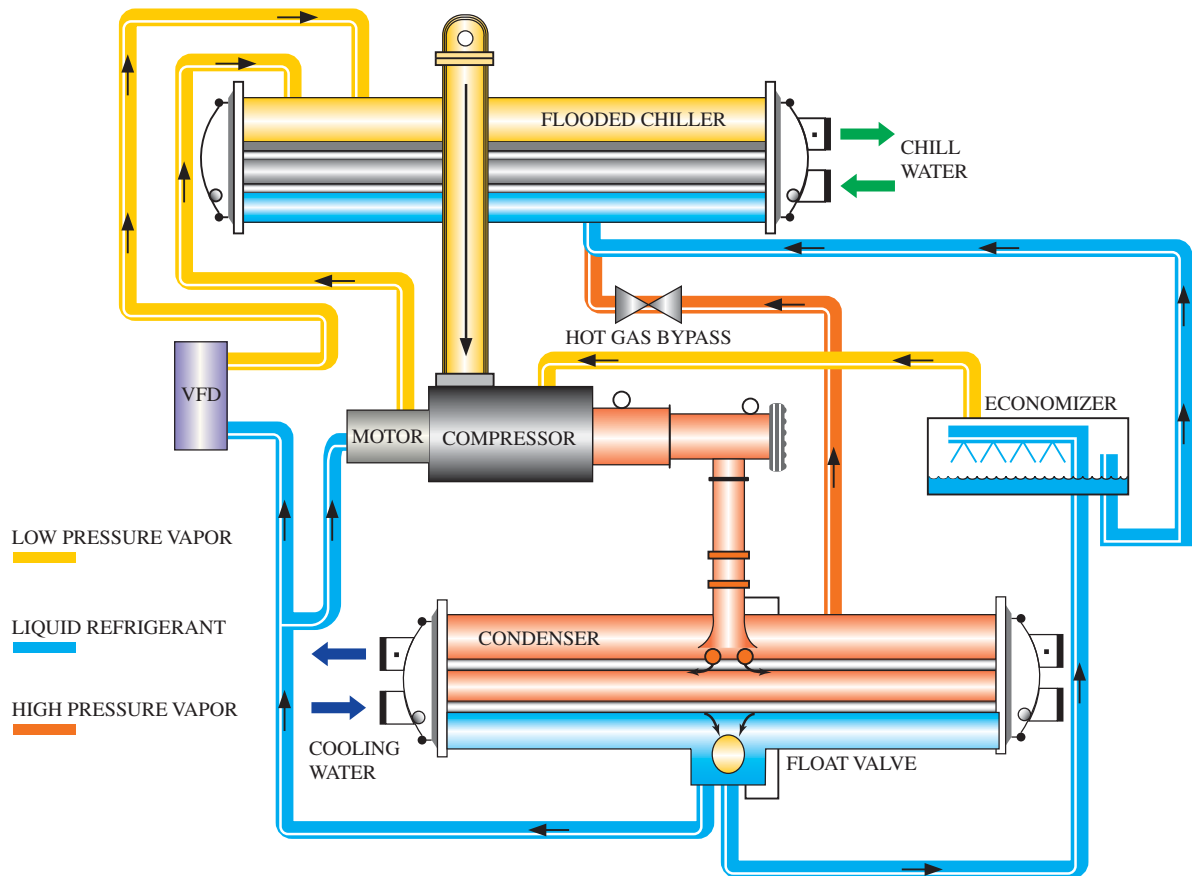

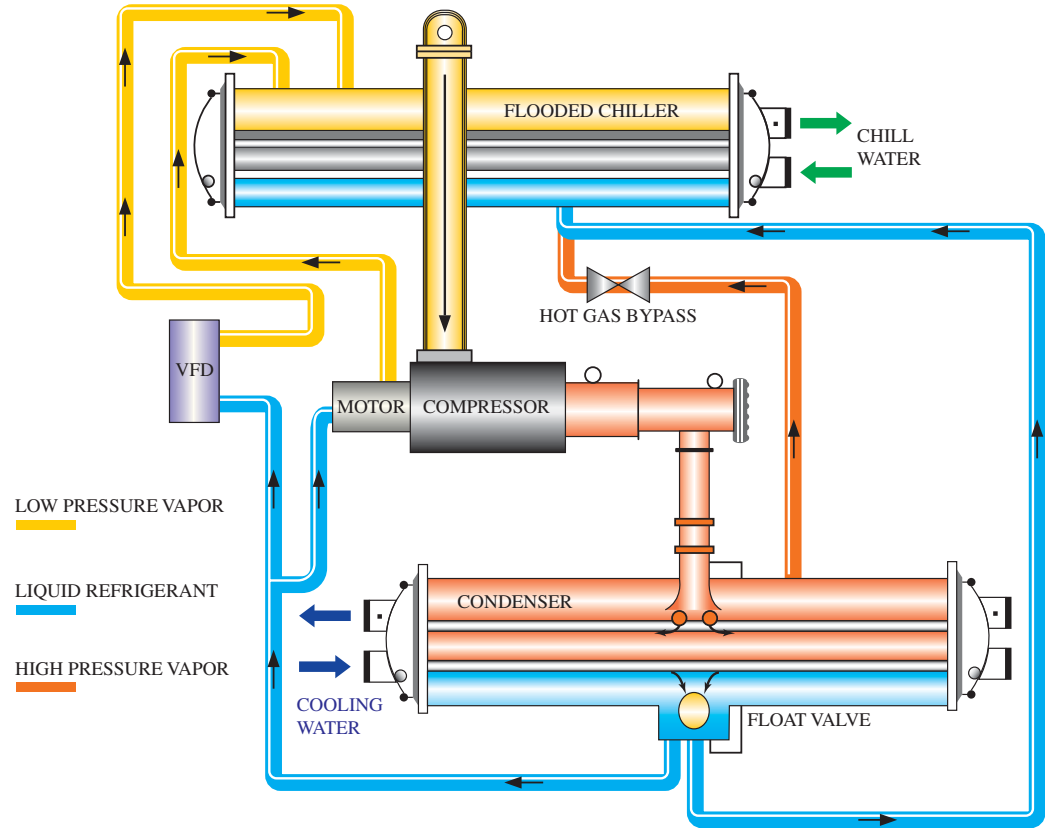

Figure 79-18 Screw compressor refrigerant flow with economizer.

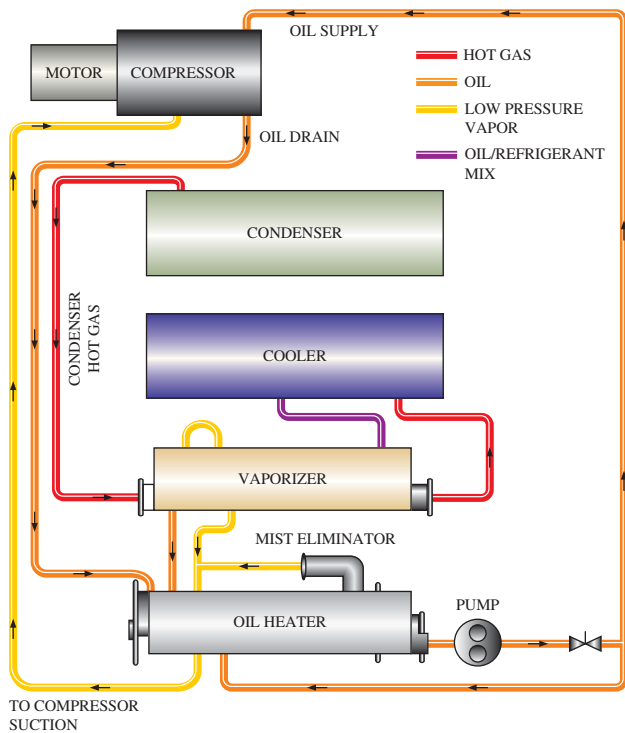

Figure 79-19 Screw compressor oil flow.

or receiver should be of sufficient size to hold the entire charge of refrigerant, and it should be rated for the same or a higher maximum working pressure as the system. Some systems have external receivers that can be used for multiple chiller circuits.

CAUTION

Always begin the refrigerant transfer from a chiller unit using liquid-recovery methods. If vapor is transferred from the chiller while liquid still remains, the chiller will freeze up and the tubes will crack to cause extensive damage to the chiller. Circulate chilled water and condenser cooling water through the unit during the recovery process to reduce the possibility of freeze-up.

An example of a transfer arrangement is shown in Figure 79-20. This system is permanently installed and can be used to transfer refrigerant from multiple chiller circuits. Chillers that do not have permanently installed transfer systems will require a portable unit. This is different from conventional portable recovery units because of the valve arrangement.

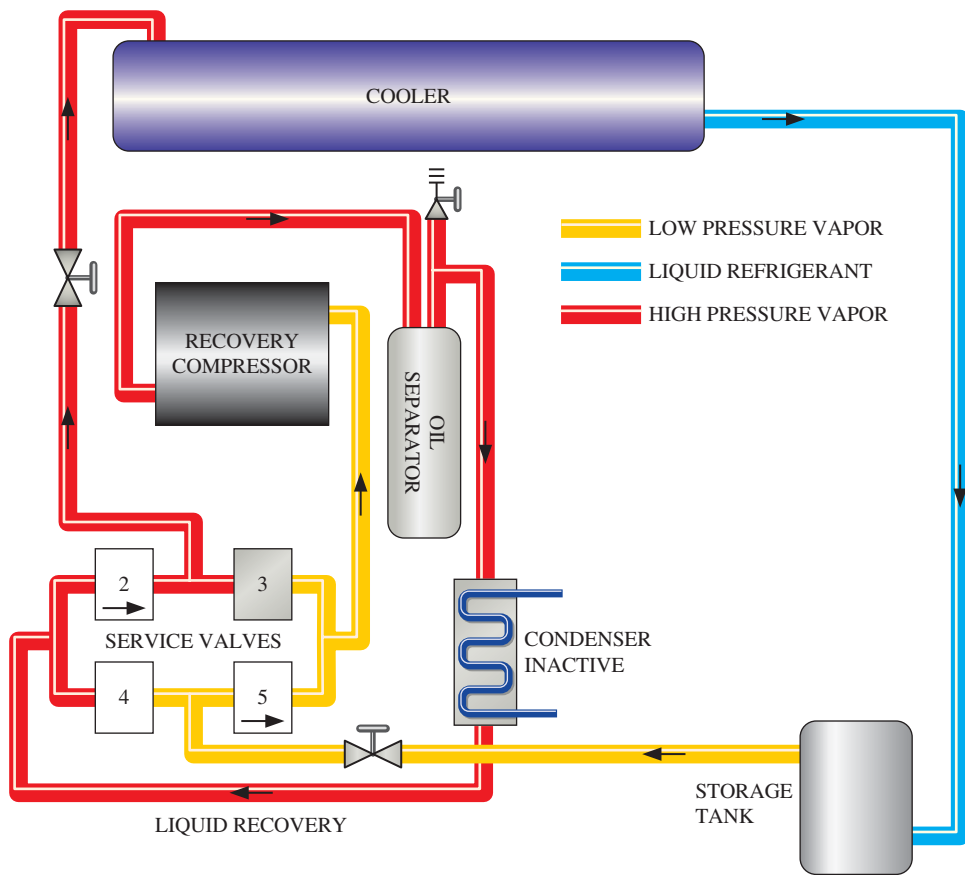

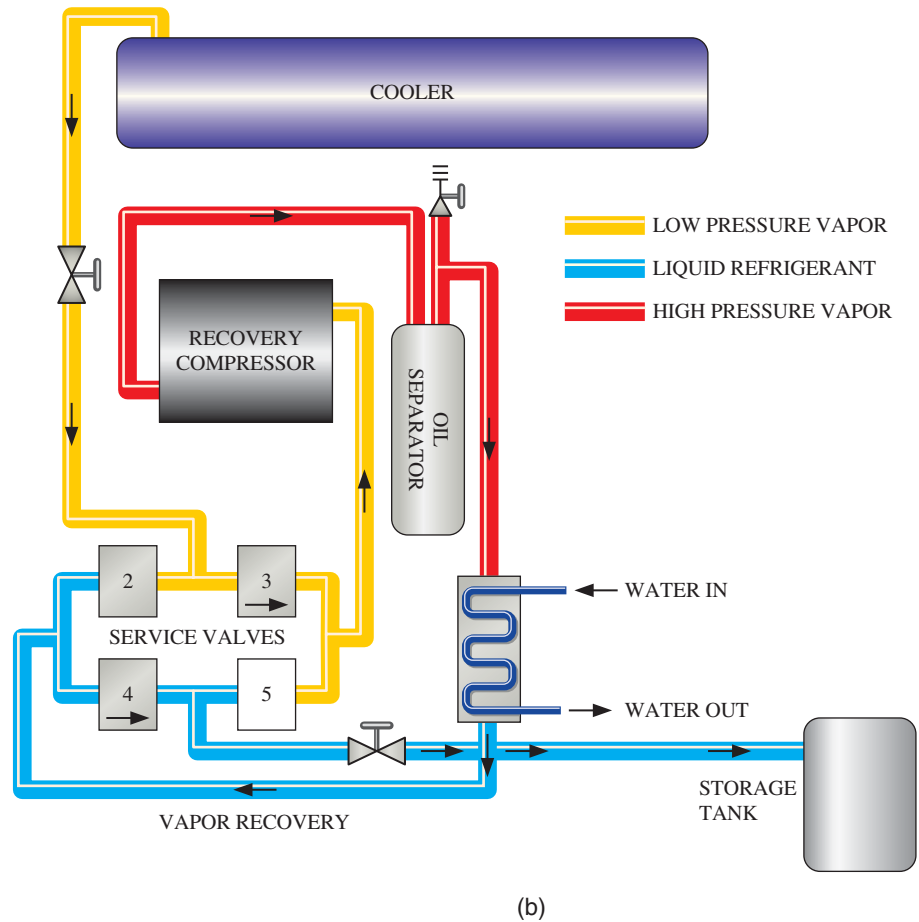

Figure 79-20a Liquid recovery first

(a)

Figure 79-20b Vapor recovery follows liquid recovery.

CAUTION

Do not mix refrigerants from chillers that use different compressor oils.

Always transfer liquid refrigerant first. Using Figure 79-20a as an example, the valve arrangement will be lined up with valves 2 and 5 open. This will allow the recovery compressor to draw suction from the top of the storage tank through valve 5 and deliver high-pressure vapor to the top of the chiller cooler or condenser through valve 2. Valves 3 and 4 will remain closed. During this liquid transfer, the recovery condenser will be inactive. The vapor entering the top of the chiller cooler or condenser will force liquid out of the bottom and to the storage tank.

CAUTION

During transfer, never fill a storage tank to more than 80 percent of capacity to allow room for expansion.

After all of the liquid has been removed from the chiller, the valve alignment will be changed for the vapor-recovery portion of the transfer, as shown in Figure 79-20b. Valves

2 and 5 will now be closed, and valves 3 and 4 will be opened. Cooling water flow will be established to the recovery condenser. The recovery compressor will draw suction from the top of the chiller cooler or condenser through valve 3. The vapor from the discharge of the recovery compressor will condense to liquid as it passes through the recovery condenser and continue through valve 4 and to the storage tank. The recovery compressor will shut down on the low-pressure cutout once the refrigerant recovery is complete. The required evacuation level is 7 psia or 15 in Hg vacuum for high-pressure chillers and 0.5 psia or 29 in Hg vacuum for low-pressure chillers.

CAUTION

Never charge liquid into a chiller that is in a deep vacuum. The refrigerant will immediately flash and the chiller will freeze up and the tubes will crack to cause extensive damage to the chiller. During the initial charge, add vapor until the chiller pressure equates to a saturation temperature above 32°F. As an example, R-123 has a saturated pressure of 5.1 psia (19.5 in Hg vacuum) at 35°F. The chiller should be at that pressure or above before introducing liquid R-123. Circulate chilled water and condenser-cooling water through the unit during the charging process to reduce the possibility of freeze-up.

79.18 ABSORPTION CHILLERS

Unlike the conventional mechanical compression refrigeration cycle used in all the other equipment discussed, an absorption chiller uses steam, hot water, or direct firing by natural gas as an energy source to produce a pressure differential in a generator section. Some absorption units generate both chilled water and hot water from the same unit. Since they can operate on waste steam or direct-fired natural gas, the actual costs of operation may be less than electrically driven equipment, depending on the relative energy costs.

SERVICE TIP

Most power companies use a building peak load as the basis for establishing the billing rate for electrical power. The peak load for electrical billing rates is based on the highest electricity usage during the prime electrical usage time of the day. Because chillers require larger amounts of energy during start-up than during operation, they must be started before the beginning of the prime cooling time. In most parts of the country, the prime electrical usage time is between 9 AM and 6 PM.

Once the peak load rate is established, it will remain in effect for all electrical usage for the next 12 months. Starting a chiller late and establishing a new higher peak rate can cost a building operator tens of thousands of dollars in higher utility bills.

Absorption chillers operate most efficiently when they run at a steady state for long periods of time. For this reason they may be one unit as part of a large building's multiple-chiller system. In a multiple-chiller installation, the absorption chiller can provide the base cooling needed to maintain the building over 24 hours, and other chillers can be started and stopped during the day as needed to meet peak cooling loads.

79.19 ABSORPTION CHILLER OPERATION

The absorption-cycle components and operational cycle are shown in Figure 79-21. The refrigerant used is simply water, and the absorbent is lithium bromide (LiBr). The evaporator shell pressure is reduced to 0.12 psia (29.7 in Hg vacuum). At this low pressure, water will evaporate at 41°F.

The refrigerant (water, colored blue) is sprayed over the outside of the chilled-water tubes in the evaporator and evaporates to remove heat from the chilled water. A strong solution of LiBr (colored orange) is sprayed into the absorber section and absorbs the water vapor. The heat given off by this absorption process is transferred to the cooling water circuit. The solution of LiBr diluted with water (colored yellow) falls to the bottom of the vessel.

The diluted LiBr solution passes through a heat exchanger and into the generator section. Heat is supplied from a heat source (hot water), through a series of coils within the generator. The water entrained in the LiBr-diluted solution is released by the heat and becomes water vapor. The water vapor passes into the condenser section,

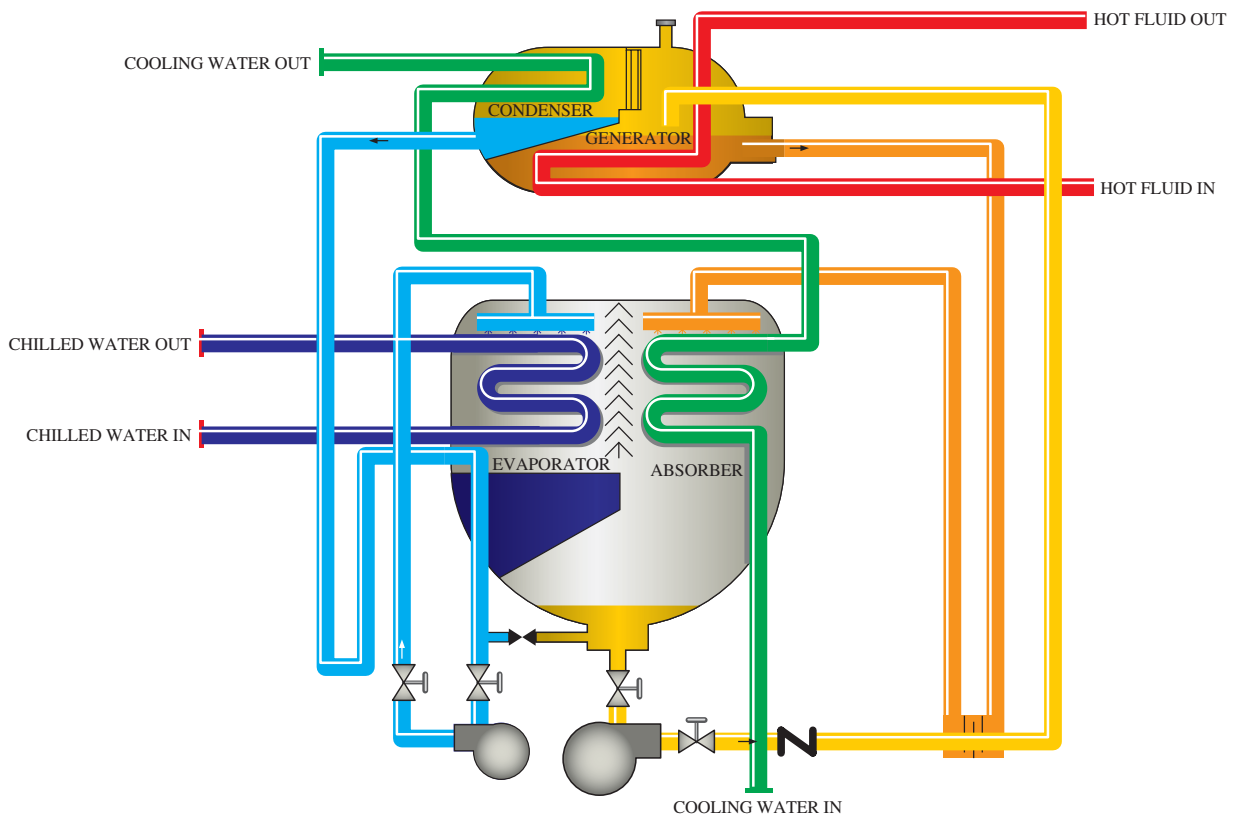

Figure 79-21 Absorption-cycle operation.

condenses back into liquid, and returns to the evaporator section. Due to the release of the absorbed water, the LiBr once again becomes a strong solution (orange) and returns via the heat exchanger back to the absorber.

UNIT 79—SUMMARY

Air-conditioning chillers are typically designed for indirect expansion. Chilled water is circulated to individual air handlers or fan rooms rather than the primary refrigerant. Chillers come in various sizes, with smaller tonnage units typically utilizing reciprocating or scroll compressors with electric motor drives. Larger tonnage units require more refrigerant flow and therefore are generally configured with centrifugal and screw-type compressors. These can also be driven by electric motors with the trend being toward variable-frequency (adjustable speed) ac drive units to increase efficiency. Other suitable drives can be diesel, steam, or gas turbine.

It is important to understand the refrigerant cycle and operation of a chiller before transferring refrigerant. Always remove liquid refrigerant from a chiller first before recovering the vapor. Failure to do this could result in chiller freeze-up and considerable damage. This also applies to charging a unit. Never charge liquid refrigerant to a chiller that is under a deep vacuum. Never raise the pressure in a chiller above the rupture disk burst pressure. Follow all manufacturer's recommendations and procedures whenever servicing a chiller.

WORK ORDERS

Service Ticket 7901

Customer Complaint: Compressor Fails to Load

Equipment Type: Light Commercial Reciprocating Chiller with Dual Compressors

The complaint is that the chiller fails to cool the building during periods of high loads. The technician arrives during the middle of the afternoon during the peak cooling period. The chiller unit is located just outside the building. The chiller operates with two four-cylinder reciprocating compressors with one in lead and the other in lag. Both compressors have cylinder head bypass solenoid unloaders. The solenoid coil on the lead compressor is warm to the touch and appears to be energized. However, the solenoid coil on the lag compressor feels cold.

The technician shuts down the lag compressor and secures its power supply while leaving the lead compressor running. The circuit is tested to ensure that the power is disconnected before the solenoid coil is removed. The coil is then tested with an ohmmeter. The coil shows infinite resistance, which indicates an open in the coil. A new coil is wired into place and the compressor starts and now loads normally.

Service Ticket 7902

Customer Complaint: Compressor Fails to Load

Equipment Type: 150-Ton Centrifugal Water-Cooled Chiller

The technician meets with the supervisor of the maintenance department and is told that the centrifugal chiller is not loading up and the chilled-water temperature leaving the unit is very high. The technician checks the temperatures and pressures registered on the unit and finds the chilled-water return temperature to be 65°F and the chilled-water outlet temperature to be 60°F. The normal chilled-water temperature outlet should be 45°F.

The compressor is a constant-speed unit operating at 12,000 rpm with variable inlet guide vanes for capacity control. The guide vanes are in the fully closed position or unloaded position. The control circuit for the inlet damper position is controlled by the chilled-water leaving temperature, so the guide vanes should be fully open, as the chilled-water temperature is high. The technician places the inlet guide vanes into manual control and slowly strokes the vanes open and closed to verify they are working correctly.

The technician follows the capillary tube from the control cabinet to the thermal bulb located in the cooler shell. The sensing line is kinked perhaps from someone stepping or dropping something on it. The sensing bulb could be easily removed without draining the chilled water from the cooler. A new sensing line and bulb are installed. The technician slowly loads the compressor with manual control of the inlet guide vanes. Once the unit is nearly fully loaded, the technician switches the control back to automatic and the guide vanes are now being controlled by the chilled-water leaving temperature.

Service Ticket 7903

Customer Complaint: Chiller Tripping on High Pressure

Equipment Type: 150-Ton Low-Pressure Centrifugal Water-Cooled Chiller

The technician checked the unit which was tripped out. The display message on the digital controller indicates a high-pressure situation. The cooling water circuit is checked and there appears to be a sufficient supply of cooling water going to the unit. Another possibility for the high-pressure condition is excessive air in the system. With the system down, the chiller pressure has risen above atmospheric. The technician uses an electronic leak detector and finds a leak at a flared fitting leading to the compressor suction pressure gauge. The fitting is tightened, and this stops the leak.

Next, the technician checks the purge recovery unit. This is a self-contained unit with a small compressor that continually removes gas from the top of the condenser, which is then condensed and returned to the unit. The

noncondensable gases collected are purged to the atmosphere. The compressor for the purge recovery unit has also tripped out. The technician resets the purge recovery unit and it begins operating normally. The technician recommends the unit to be checked regularly for leaks. The purge recovery unit also needs to be monitored because it is an older unit and could be in need of replacement soon.

UNIT 79—REVIEW QUESTIONS

1. Describe the difference between a flooded and a dry (direct expansion) type cooler.
2. What are some advantages and disadvantages of flooded coolers?
3. Why are low-pressure refrigerants well suited for centrifugal compressor chillers?
4. What is the function of a purge recovery unit?
5. What precaution should be taken whenever leak testing a low-pressure chiller?
6. What precaution should be taken for coolers that are located outside?
7. Why is a cooler shell and suction line insulated on a unit that is located indoors?
8. Explain the operation of lead and lag compressors.
9. How can the centrifugal compressor speed be higher than the motor speed?
10. What is the difference between a single-stage and two-stage centrifugal compressor?
11. What is the most efficient method of capacity control for a centrifugal compressor?
12. What types of prime movers can be used for centrifugal chillers?
13. What type of capacity control is used for a centrifugal compressor that is driven by a constant-speed motor?
14. What can be considered an advantage of a screw-type chiller as compared to a centrifugal chiller?
15. What is the advantage of a screw-type compressor that utilizes three screws?
16. What is the purpose of a chiller economizer?
17. What happens to the flash gas formed in a chiller economizer?
18. What is the purpose of an oil-return system for a chiller?
19. How should refrigerant be transferred from a chiller?
20. What could happen if you charge liquid refrigerant into a chiller that is under a deep vacuum?

UNIT 80

Hydronic Heating Systems

OBJECTIVES

After completing this unit, you will be able to:

1. list the common types of terminal units used for hydronic heating systems.
2. list the different types of piping systems that can be used for hydronic heating.
3. explain how a multiple-zone heating system is configured.
4. describe the operation of a motorized valve used for hydronic heating systems.
5. list the advantages of radiant floor heating.
6. describe the operation of mixing valves.
7. select a proper circulator for a heating system.

80.1 INTRODUCTION

Hydronics can be defined as a science that utilizes water or steam to transfer heat from the source where it is produced to an area where it can be used through a closed system of piping. Depending on the application, it may be desirable to circulate hot water to radiant heaters, fan coil units, or air handlers located throughout a building. Water-to-water and air-to-water heat pumps are also examples of hydronic heating systems. Another method growing in popularity is radiant floor heating where hot water is piped through the floor. To service and install hydronic systems, it is important to understand how these systems are configured and what advantages and disadvantages these have over other alternative heating methods.

80.2 HYDRONIC SYSTEM SELECTION

The decision to install a hydronic heating system should be weighed against all other available alternatives. Although water can be circulated by gravity, modern heating systems use forced circulation, which requires an electrically driven pump or series of pumps. Therefore, the installation of a hydronic system will generally require an extensive network of piping. The common choice for piping in the past was copper, which required the fitting and soldering of varied lengths, and this was a time-consuming process. New materials that are much easier to work with, such as cross-linked polyethylene tubing, have sped up the installation process.

The advantages of hot-water heating systems are based on overall comfort for the following reasons:

- Heat is supplied at the base of the outside wall, warming the interior wall surface by convection and conduction to near room temperature. This prevents the uncomfortable feeling of losing body heat to cold outside walls.
- The natural circulation of warm air rising from the radiant heaters supplies heat to the room by convection with a gentle movement of air. This prevents uncomfortable drafts and air velocities that

absorb moisture from the skin, creating a cooling effect.

- The hot water heats and cools slowly. This prevents sudden changes in temperature.

The disadvantages of hot water heating are as follows:

- It costs more than an equivalent warm-air installation.
- If humidification and air filtration are desired, a separate air system needs to be installed.
- If cooling is desired as well as heating, dual systems are required.

80.3 WATER AS A HEAT-TRANSFER MEDIUM

Water expands and contracts as its temperature changes. In a liquid state, the change in volume with temperature is relatively small, but this can still be significant in a closed-loop system. Therefore, in closed hot-water heating systems, to allow for expansion, certain safety measures are provided as follows:

- Both temperature- and pressure-limiting controls are used to maintain the water within safe conditions.
- A pressure-relief device is supplied in the piping to relieve excess pressure should it occur.
- An expansion tank is provided in the piping, partly filled with air, to permit normal expansion and contraction of the water.

Water will freeze into ice at temperatures around 32°F, depending on the pressure. As water freezes, it expands and can burst pipes or containers. Provisions need to be made to do the following:

- Prevent the water from reaching the freezing point.
- If the water cannot be prevented from reaching the freezing point, use an antifreeze solution in the system in place of pure water, to lower the freezing point to a safe value.

Water has considerable weight (62.3 lb/ft^3), and allowances often need to be made in the supporting structure for equipment containing water. Water has friction as it flows through piping, fittings, and equipment. This frictional force must be considered when selecting the flow of a circulating pump.

CAUTION

It is not easy to drain all of the fluid out of hydronic system pipes for service. Sometimes water can be trapped and then be released suddenly as the result of vibration from shaking the pipe or when air breaks the siphon. It is important when working on electrical components such as pump motors that you make certain that the power to the pump is off and all the water in the system has been removed. A sudden gush of water can create a major safety hazard from electric shock if these precautions are not taken.

80.4 HYDRONIC SYSTEM RESIDENTIAL APPLICATIONS

A hydronic heating system for residential use often includes a gas- or oil-fired boiler. The boiler will be piped with the proper accessories to allow for expansion, water makeup, and mixing valves for different types of zone heating applications. This typical arrangement is shown in Figure 80-1. The hot water leaves the boiler through a 2-in supply valve and is circulated throughout the building. The water returns to the boiler from a 2-in return line and through a circulating pump. In this example, the water is pressure fed into the boiler by the circulator pump. There are a number of different design types, with another common example being a

straight gravity return line without a circulating pump. Also note the expansion tank and an air vent located in the return line. The cold-water inlet is for the makeup water. This will be connected to the house water supply plumbing. A pressure-reducing valve is used to regulate the water admitted into the boiler. The boiler is equipped with a pressure-relief valve. There are shutoff valves to isolate different parts of the system and to drain lines for use when servicing or repairing the system.

TECH TIP

The term *radiator* has been a commonly used term for heating systems. Although this term is commonly accepted, it is misleading because it implies that the heat transfer is through radiation, which is incorrect. Heat transfer from terminal units is through conduction (heat transfer through a solid substance) and convection (heat transfer through a fluid). This means that air circulation for convective heat transfer is critical for proper operation. Radiant floor heating also has this same type of misleading terminology; and heat transfer for this type of installation likewise depends on convection and conduction. A radiant floor heating system placed beneath a thick carpet will be less efficient than a radiant heating system placed beneath a tile floor due to the conductive heat transfer properties of the different materials.

80.5 TERMINAL UNITS

Terminal units transfer heat from the hot water to the various building areas. The heat supplied by these units is controlled to provide comfortable conditions. Normally this

Figure 80-1 Hydronic boiler piping arrangement.

Figure 80-2 Copper tubing and aluminum fins.

equipment is rated in BTU/hr or MBTU/hr; however, these ratings can be stated in terms of equivalent direct radiation (EDR). For hot-water systems, $1 \text{ ft}^2 \text{ EDR} = 150 \text{ BTU}$, based on an average water temperature of 170°F . Hot-water units are rated based on the water temperature drop through the unit, which can be 10°F – 30°F . A number of types of terminal heating units are available, including baseboard units, convectors, fan coil units, and radiators.

Baseboard Units

Baseboard units are installed near the floor on the outside walls of each room. Heat is supplied by conduction and convection. The heating element is finned-tube construction or cast iron. The most common units have elements using copper tube and aluminum fins, as shown in Figure 80-2. A typical finned tube along with accessory pieces for corners and ends is shown in Figure 80-3.

Convector Units

Convector units such as the one shown in Figure 80-4 can be freestanding or recessed. These units heat the room mainly by convection, with the air entering the bottom and leaving from the upper front. The freestanding model is

Figure 80-3 Trim pieces for baseboard enclosures.

Figure 80-4 Typical convector.

Figure 80-5 Horizontal fan coil.

supplied either with a flat or slanting top. An adjustable damper can be supplied if desired.

Fan Coil Units

Fan coil units as shown in Figure 80-5 can serve the same function as convectors, but they have additional features and increased efficiency. The unit has a centrifugal fan with manual speed control for circulating the room air through the unit. Air filters are standard equipment. The unit is often used for both heating and cooling. Outside air can be supplied through the back of the unit. Units are available with air volume ratings from 200 to 1,200 CFM and hot-water heating capacities from 7.6 to 112 MBTU/hr.

Radiators

Cast-iron radiators are primarily used for steam installations (Figure 80-6). They were used more frequently in past years. Hydronic systems are sometimes configured to work with existing cast-iron radiators. These typically operate with water temperatures of 125°F to 200°F .

(a)

(b)

Figure 80-6 (a) Cast-iron radiator front view; (b) side view.

80.6 RADIANT FLOOR HEATING

Radiant floor heating has been recently growing in popularity, although this type of heating has a long history. The Romans were the first to use this type of heating. American architect Frank Lloyd Wright used radiant floor heating in many of his home designs from the 1930s. Radiant floor heating is more comfortable than conventional heating because it directs the heat to the occupant level and less heat is wasted up near the ceiling level, as shown in Figure 80-7.

(a)

(b)

Figure 80-8 (a) Radiant floor manifolds with individual flow control; (b) manifold flow meters.

There are also no baseboards or radiator panels offering obstruction to furniture. This allows for more effective use of wall space within the room. Radiant floor heating is also quiet when compared to the fan noise levels found with a forced-hot-air system.

Radiant heat piping will have a number of heating loops distributed through a manifold, as shown in Figure 80-8. Often cross-linked polyethylene pipe is used because it is flexible and relatively easy to connect. The piping can be placed into the poured concrete slab for the building. This works well, as the entire slab heats evenly to provide for a continuous and prolonged heat sink. For upper stories

Figure 80-7 Radiant floor temperature comparison.

of the building, the piping can be installed under the floor through the floor joists. This type of installation can be performed after the building is complete by drilling through the floor joists and installing the piping. This can also be installed during the initial construction of the building.

TECH TIP

Radiant floor heating can heat effectively with water temperatures as low as 90°F to 105°F. This allows lower boiler temperatures and increased operating efficiency.

80.7 TYPES OF PIPING SYSTEMS

Hot-water heating systems can be installed with a variety of piping arrangements. Each of these arrangements controls the supply of hot water from the boiler to the terminal units (and the return) in such a way that comfortable conditions are produced. The common systems for hot-water heating applications in residential and small commercial installations are each briefly explained.

Series Loop, Single Circuit

The series-loop system is probably the simplest of all the piping arrangements. A schematic diagram of the single-circuit piping layout is shown in Figure 80-9. In this piping system, the main supply pipe from the boiler enters the first baseboard unit. The outlet from the first unit is connected directly to the inlet of the second unit. This arrangement is continued until all baseboard sections are connected in series. The outlet from the last section is connected to the circulator pump, which connects to the boiler. Thus, all the water flowing through the system passes through each unit.

In many cases, the bathroom or kitchen does not have enough wall space for the proper length of baseboard heating, so a convector is used in place of the baseboard. The convector can be tied to the system using a venturi fitting (see Figure 80-9). The convector is the first terminal unit after the boiler. The venturi is simply a restriction in the line that

ensures that some water will flow through the convector, which is in parallel with the other terminal units in the circuit.

When these systems are installed, the entire perimeter of the building has baseboard enclosures. The amount of finned-tube element placed in these enclosures is dependent on heat-loss requirements. Where the main pipe passes a doorway, an offset is made in the piping to run it down below the floor until it passes the door opening to come up again on the other side.

With this piping arrangement, each downstream unit is supplied with cooler water than the preceding one. The actual hot-water temperature drop between terminal units is about 2°F. To compensate for this, each successive unit is oversized by about 2 percent. The use of a series-loop system reduces the cost of the installation to a minimum.

Series Loop, Double Circuit

On larger systems, better performance can be obtained by dividing the system into two (or more) approximately equal circuits (Figure 80-10). When this is done, balancing valves are installed in each branch to permit adjustment of the flow.

One-Pipe Venturi System, Single Circuit

The one-pipe venturi fitting system has a single main line extending from the supply to the return connection of the boiler. The terminal units are fed by a supply and return branch connected to the main, as shown in Figure 80-11. The supply connection uses a standard tee, and the return connection uses a special venturi fitting. The venturi creates a negative pressure at the main connection, drawing the necessary flow through the branch.

This system differs from the series loop in that only a portion of the total flow enters the terminal unit. There is still a temperature drop in the main line as it reaches the location of successive units. The reduced flow, however, improves the performance of the terminal units.

One-Pipe Venturi Unit, Double Circuit

On larger systems using this piping arrangement, better performance can be obtained by dividing the system into

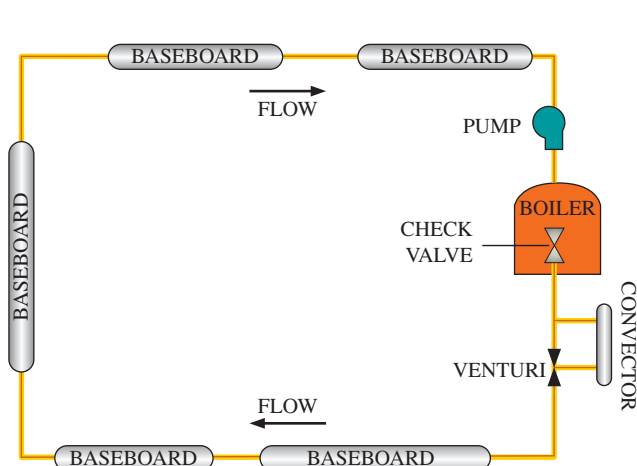

Figure 80-9 Series loop piping layout, single circuit.

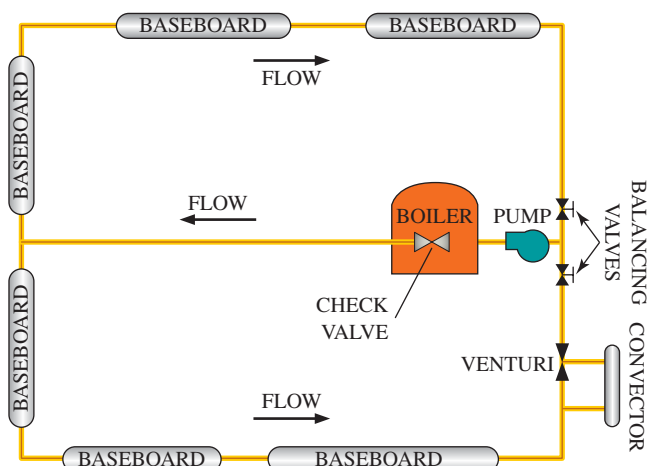

Figure 80-10 Series loop piping layout, double circuit.

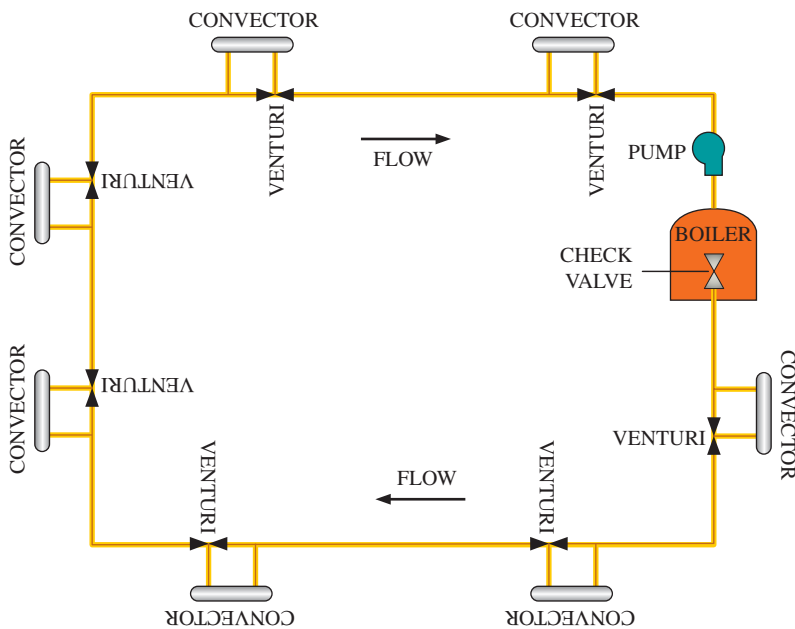

Figure 80-11 One-pipe venturi system, single circuit.

Figure 80-12 One-pipe venturi system, double circuit.

two (or more) approximately equal circuits (Figure 80-12). When this is done, balancing valves are installed in each branch to permit adjusting flow.

Two-Pipe System, Direct Return

In the two-pipe system, separate supply and return mains are used. The return water from the terminal units is collected and returned to the boiler. With this piping arrangement, each unit will receive the same supply-water temperature.

With the direct return, the two mains are run side by side with a supply branch run to each unit from the supply main and a return branch run from each unit to the return main. The first unit taken off the supply main is the first unit on the return main before it reaches the boiler

(Figure 80-13). Obviously, the shortest piping is used on the unit nearest the boiler. The longest piping is used on the unit farthest from the boiler. This difference in piping pressure drop must be equalized by using a square head cock in either the supply or return branch to each unit.

The two-pipe direct system uses more pipe than the one-pipe system; however, it is considered to be more efficient by providing better water distribution and better control. This system can also be designed using two or more circuits.

Two-Pipe System, Reverse Return

The two-pipe reverse-return system is similar to the direct return system except that the piping is arranged so that the same length of pipe (supply + return) is used for each

Figure 80-13 Two-pipe direct-return system.

terminal unit. This is accomplished, as shown in Figure 80-14, by taking the unit nearest the boiler off the supply main first, connecting it to the return main last, and proceeding on this basis to equalize the piping lengths for all units. This equalization of the piping loss to each unit provides a balanced condition so that each unit receives its proper share of water.

80.8 ZONED SYSTEMS

Zoning is provided where it is desirable to control the supply of heat (hot water) to different areas of the building by separate thermostats. The areas selected can be determined

by usage or building orientation. For example, to zone by usage, the living areas of a residence can be placed in one zone and the sleeping areas in another. To illustrate orientation zoning, a small commercial building can place all the rooms with southern exposure in one zone and the rooms with northern exposure in another. Whatever separation is made, allowance must be made in the piping and controls to provide this feature.

One advantage of hydronic heat is that installing a zoned heating system is relatively easy. Each heating zone has its own piping loop. One way to control water flow to the zones is by a motorized zone valve (Figure 80-15). The zone valve is a normally closed electrically operated valve. A zone thermostat controls the zone valve, opening it when

Figure 80-14 Two-pipe reverse-return system.

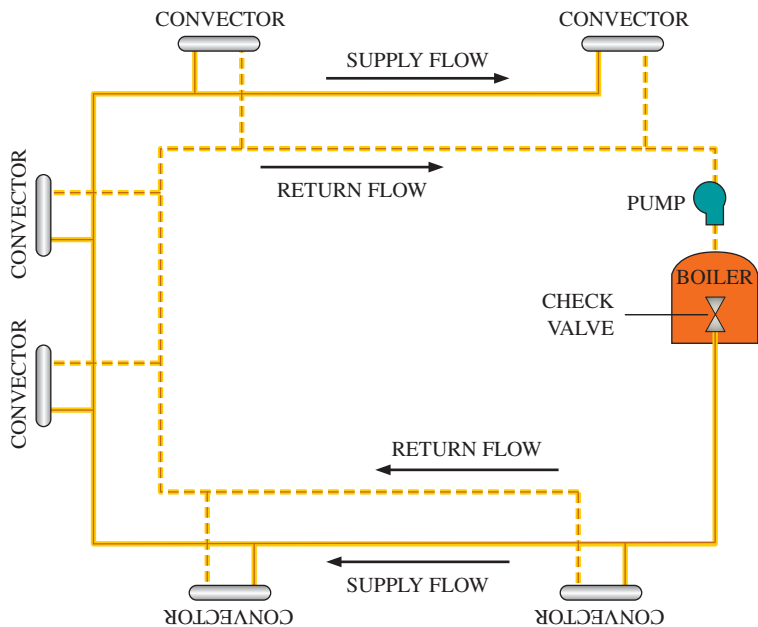

Figure 80-15 Motorized zone valve.

Figure 80-16 Zone valve wiring.

there is a call for heat. The zone valve has a set of contacts that close to energize the circulator pump, providing heat for the zone. The contacts for the valves are wired in parallel with each other so that any of the zone valves can energize the pump (Figure 80-16). This arrangement allows individual temperature control of multiple zones without complex controls and with relatively low installation cost.

There are many ways to pipe a zoned hydronic system. A major design challenge is to ensure steady water flow for even heat distribution. A simple method of achieving this is called reverse return. In reverse-return piping, the zone with the shortest distance to the hot-water supply has the longest distance to the return.

Figure 80-17 shows a typical piping system using zone valves. Balancing valves are used to compensate for different pressure drops and different load requirements. A balancing valve is placed in series with each zone, allowing the pressure drop through each zone to be adjusted.

Another way to control the flow of hot water in each zone is to provide a separate circulator for each zone, as shown in Figure 80-18. Any one of the systems previously described can be provided with zoning. The circulator in each zone responds to the requirement of the thermostat in that zone.

Figure 80-17 Zoned hydronic system piping.

Figure 80-18 Zoned system using separate circulators for each zone.

TECH TIP

A zoning hydronic system can have a significant energy savings in two ways. It provides heat only where it is needed, and the thermal mass of the water within the system will allow the heating unit to operate for longer periods of time, even during light loads. As the water in the system is heated and the heat is used at a terminal unit located in a zoned area, the boiler may cut off and remain off for a period of time while the circulating pump still provides hot water to the zone. The boiler will not re-light until the water temperature has dropped below the upper setpoint. This allows for longer boiler run times, which increases the overall operating efficiency.

80.9 RESIDENTIAL ZONE HEATING

Figure 80-19 shows the configuration for a multiple-zone system. As an example, zone 1 could be the basement, zone 2 the first story of the house, and zone 3 the second floor. Each zone would have its own thermostat. The upstairs bedrooms could be easily maintained at a lower temperature than the downstairs living spaces. This system has a separate circulator pump supplying water to each zone as well as a circulator on the return circuit to the hot-water boiler.

The boiler shown in Figure 80-20 has a circulator pump that delivers water from the boiler to the zone circulator pumps. When the zone calls for heat, the circulator pump for the zone will run. In this way, if zone 1 is running and then zone 2 comes on, there should be little reduction in the supply to zone 1.

The boiler in Figure 80-21 uses zone control valves instead of individual circulator pumps for the zones. One circulator pump will supply both zones. This type of system utilizes fewer pumps, thereby reducing installation costs and electricity usage. When the zone calls for heat, the zone control valve will open and the circulator pump will run. One apparent disadvantage should be evident. If zone 1 is running and then zone 2 comes on, there could be a reduction in the supply to zone 1.

The determination for the number of zones and the placement of circulator pumps depends on a number of factors. One is the personal preference of the homeowner. Every room could be a separate zone if desired. However,

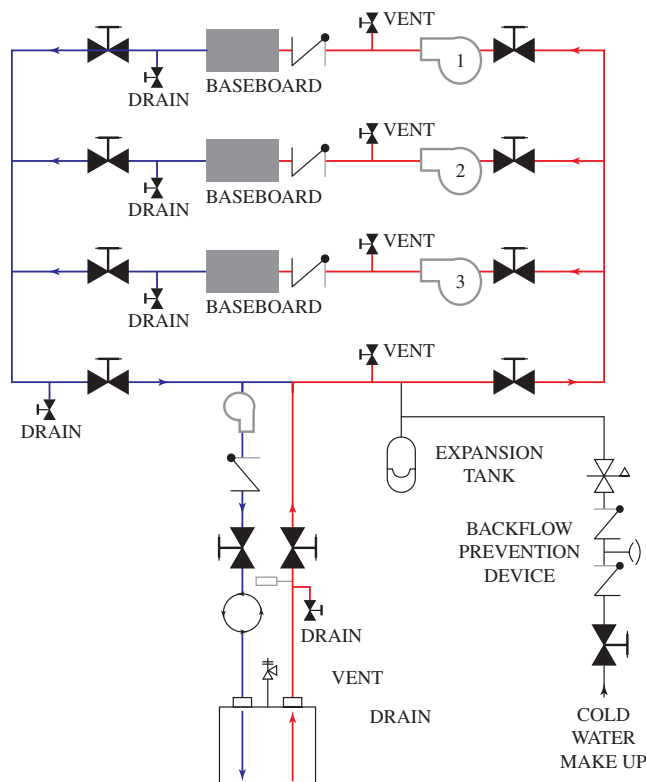

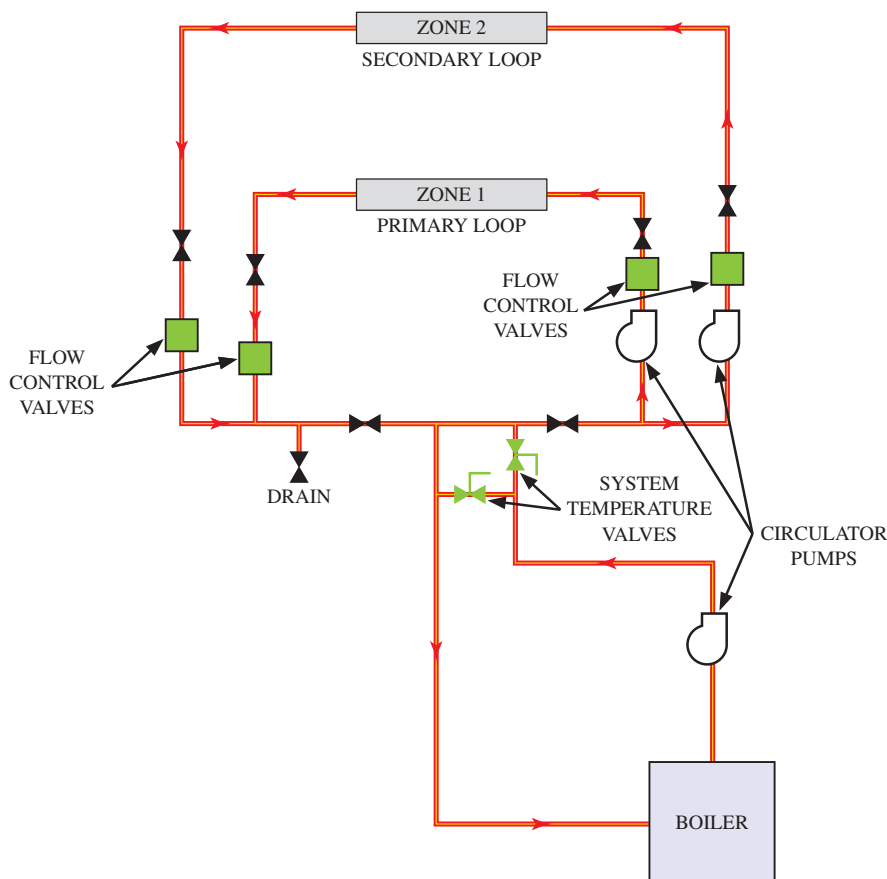

Figure 80-19 Multiple zones using circulators for supply and return.

Figure 80-20 Multiple zones with circulator pumps.

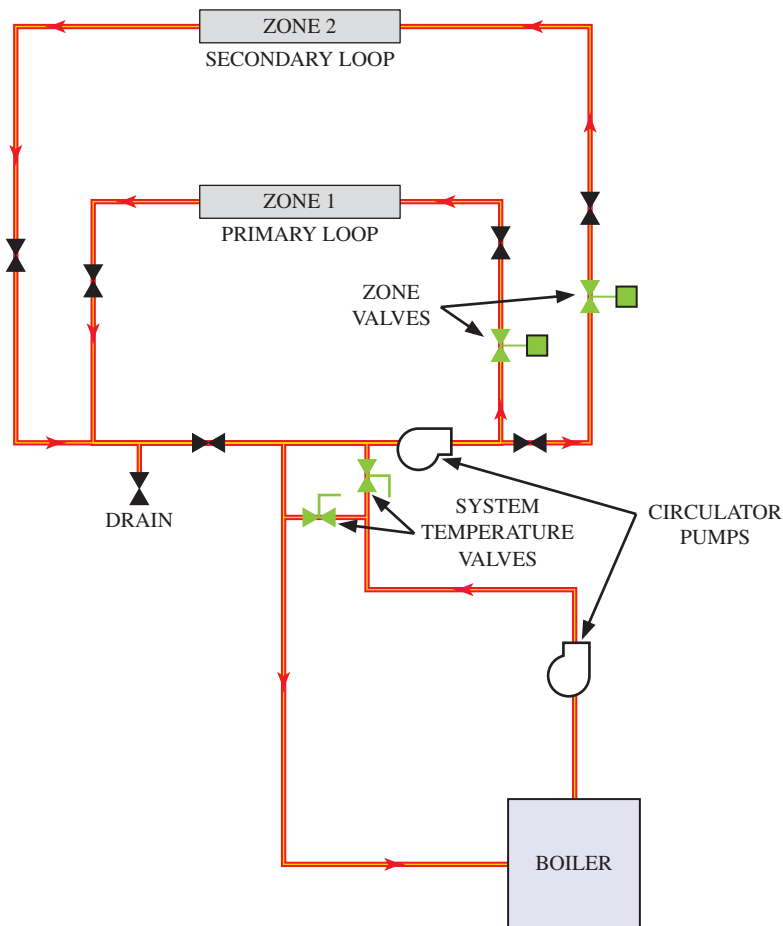

Figure 80-21 Multiple zones with zone control valves.

this would involve a complex series of piping and zone valves or circulator pumps. It is not unusual for a house to have two zones. The first floor and second floor are often the two zones. One circulator pump with zone control valves may not be sufficient to deliver the water to both the first and second floor. In this case, individual zone pumps may be required. If the house is a single-story building with two zones on the first floor, then one circulator pump with zone control valves may prove to be sufficient.

80.10 ZONED SYSTEM, USING MOTORIZED VALVES

The zoning arrangement using motorized valves is similar to the system with pump zoning, with the exception that the motorized valves control the flow in each zone. Each supply circuit has a motorized valve controlled by the thermostat in that zone. A motorized valve can also be used as a bypass around the circulator pump to relieve the pressure when only one zone valve is open.

The cross-sectional view of a motorized zone valve, as shown in Figure 80-22, can be used to describe its operation. When the thermostat contacts close on a call for heat, the 120/24 V transformer is energized. The heating element wrapped around the wax-filled element in the power head heats up. The heated expanding wax pushes down on

Figure 80-22 Heat motor valve cross-section.

the valve stem and water begins to flow through the valve to the zone. The stroking action of the valve stem piston closes electrical contacts to complete the circuit through terminals 2 and 3. This triggers a relay to start the circulator pump. The opposite sequence occurs when the thermostat contacts open.

80.11 MIXING VALVES

Mixing valves are used to mix the hot boiler water with the cooler return water (Figure 80-23). These can be used for different purposes. As the outdoor temperature drops, the supply-water temperature can be increased due to the greater heating demand. The higher the water temperature, the higher the heat output at the terminal unit. At higher outside temperatures, less heating is required and the mixed water temperature can be lowered, providing energy

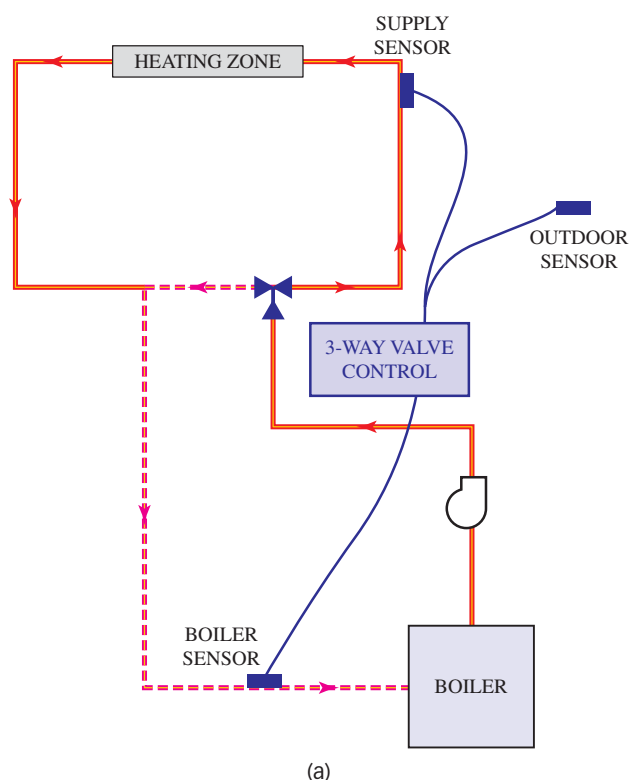

(a)

(b)

Figure 80-23 (a) Cutaway view of mixing valve; (b) mixing valve with a metering scale marked on the outside.

(a)

(b)

Figure 80-24 (a) Three-way mixing valve circuit; (b) three-way mixing valve with outside temperature control.

savings. A three-way mixing valve with outside temperature control is shown in Figure 80-24.

Another application of a three-way mixing valve is for radiant floor heating. The temperature setpoint of the hot-water boiler may be higher than the temperature required for the radiant loop. Generally, radiant floor heating loops operate at much lower temperatures than baseboard or convectors. The mixing valve will control the final temperature to the radiant loop, as shown in Figure 80-25.

80.12 CIRCULATOR PUMPS

The pumps used for hydronic heating systems are usually the centrifugal type (Figure 80-26). These are referred to as non-positive displacement pumps. Unlike a gear-type pump, a centrifugal pump can be operated with the discharge valve

Figure 80-25 Three-way mixing valve operation for radiant loop.

Figure 80-26 Horizontal centrifugal pump.

closed. This is called the pump shutoff head. However, if the centrifugal pump operates for an extended period of time with the discharge valve closed, it will overheat due to the fluid friction developed.

Flow Rate

The principle of operation for a centrifugal pump is shown in Figure 80-27. The pump motor spins an impeller, which can be similar to a flat disk with vanes (Figure 80-28a). This is called an open impeller. There are many different sizes and types of impellers, as shown in Figures 80-28b–d. The spinning impeller increases the water velocity, thereby making

Figure 80-27 The spinning impeller will increase the velocity of the water through the pump.

(a)

(b)

it flow out of the pump and through the piping. The flow of water is measured in gallons per minute (gpm).

Head Pressure

The weight of water in a pipe or tank exerts a force. As the height of water in a pipe or tank becomes greater, the force increases. This force can be measured as a pressure and is often referred to as head pressure. The units of head pressure are commonly expressed in feet rather than psi. The height of the water column is used to determine the head pressure. One foot of water exerts a pressure equivalent to 0.433 psi. The pressure as measured by a gauge

Figure 80-29 Relationship between tank size and head pressure.

at the bottom of an open water tank 20 ft high would be equal to:

$$20 \text{ ft.} \times 0.433 \text{ psi/ft} = 8.66 \text{ psi}$$

The solution shows that a pressure gauge at the bottom of an open water tank 20 ft high would read 8.66 psig. The diameter of the tank does not matter, just the height (Figure 80-29). This is because the pressure measured is per square inch, and 1 in² of area in a 10-ft diameter tank is the same as 1 in² area of a 5-ft diameter tank. It must be understood then, that the head pressure of a 1-in diameter pipe is the same as the head pressure in a ½-in-diameter pipe if both are 20 ft high. For quick estimates, the relationship between water height and pressure is almost two to one. 100 feet of water would have a pressure at the bottom of about 50 psig. However realize that the more accurate measurement would be $100 \times 0.433 = 43.3$ psig.

Head Pressure and Flow

Head pressure is measured in feet of head or psi, and flow is measured in gpm. When a pump is required to pump water higher and higher, the head pressure will increase. The head pressure required to deliver water from the basement to the third floor will be much higher than the head pressure required for delivering water from the basement to the first floor.

As the head pressure increases, the total flow (gpm) through the pump decreases, as shown on the pump performance curve in Figure 80-30. This pump with would be able to deliver approximately 18 to 19 gpm with 8 ft of total head. Some pumps such as this are designed for high flow rates and low head pressures. These are ideal for applications where a lot of water is required that does not have to travel too far or too high. Other pumps are designed with high head pressures but lower flow rates, as shown on the pump performance curve in Figure 80-31. These are ideal for applications where less flow is required but the water has to be delivered to the second or third floor of the building.

Figure 80-30 As head pressure increases, the pump flow rate decreases.

Figure 80-31 Pump designed for high head pressure but relatively low flow rate.

Pumps are selected to perform a specific purpose, providing the proper flow at a pressure to overcome the resistance of the circuit in which they are placed. Manufacturers provide pump design data, and it is important to select the proper pump depending on the application. An example of a performance chart for an assortment

Figure 80-32 Typical performance curves for centrifugal pumps.

of circulator pumps is shown in Figure 80-32. This allows for matching the most suitable pump to meet the system requirements.

Pump Performance Curves

It is also important to note that pump efficiency will change at any point along the performance curve. The total head pressure and flow rates developed are determined to some extent by the impeller diameter and the brake horsepower (bhp) rating of the pump. A larger-diameter impeller requires a greater bhp and will produce more flow and higher head pressures as compared to a smaller-diameter impeller and lower bhp pump. It is important to note that the best efficiency is not at the maximum head pressure or the maximum flow rate but usually somewhere between the two. As an example, one model of pump rated at 7.5-bhp with an 8.25-in diameter impeller would have a maximum efficiency of over 80 percent at a total head pressure of approximately 46 ft and a flow rate of 400 gpm. If the total head pressure increases to 50 ft and the flow rate drops to 325 gpm, then the efficiency for this pump would drop to less than 77 percent. The same is true if the total head decreases and the flow rate increases.

80.13 TROUBLESHOOTING PUMPS

A common troubleshooting problem is pump noise and vibration. This is a nuisance and the vibration can cause the piping to fatigue and break over time. If the pump loses its prime, its impeller can overheat and become so damaged that the pump will not work. Common causes of pump noise and vibration are misalignment, air entrainment, and clogged strainers.

Pump or System Noise

Noise could be the result of a shaft misalignment which would need to be checked and then realigned if necessary. A worn coupling can lead to noise and if this is the cause it will need to be replaced and the shaft realigned. The same is true for worn pump or motor bearings which may require lubrication or replacement.

Improper pump foundation installation or loose bolting will cause noise. Piping strain due to expansion and contraction can lead to loose foundation bolts. In this case additional hangers may be required or the piping may need alteration. Improper motor speed or rotation or a clogged strainer or impeller can also lead to noise.

The actual pump performance may need to be compared to its design specification to determine if the pump impeller is the correct size. If the pump is operating close to or beyond the end point of its performance curve, noise can result. Excessive throttling of balance or control valves will lead to high water velocity and noise.

Cartridge-Type Circulator Pumps

Some small circulator pumps used in hot-water systems have replaceable cartridges, such as the one shown in Figure 80-33. The replacement cartridge contains all the moving parts and allows the pump to be serviced instead of replacing the entire unit (Figure 80-34). It is self-lubricating and contains no mechanical seal. When troubleshooting this type of pump, the motor windings can be easily inspected. Notice the charred burnt windings of the motor and the discoloration of the capacitor (Figure 80-35).

Figure 80-33 Cartridge-type circulator pump.

Figure 80-34a Pump cartridge and motor.

Figure 80-34b Motor and pump cartridge being removed from the pump housing.

Inadequate or No Circulation

This is often the result of an improperly filled system that is air bound. Typically the vent piping, make up feed regulator, or expansion tank may be at fault. It is important to get all of the air out of the piping system before leaving the job.

(a)

(b)

Figure 80-35 (a) Burnt-out motor shown on the right; (b) discoloration of the capacitor shown on the right.

Figure 80-36 Automatic air-purge valves are located at the high points of the radiant heat piping loop.

Air trapped in the system can cause noise and may result in the water pump losing its prime. Radiant piping systems will often have automatic venting valves located at the high points of the circulating water loop (Figure 80-36). If it is determined that air is not the problem, then another possible cause is a clogged suction strainer.

TECH TIP

Circulating pumps on closed-loop systems only work against the vertical lift head when the system is initially being filled. Once the system is completely filled with water, the pump effective head (discharge head – suction head) is only the flow resistance of the piping system itself. The suction head developed from a height of 10 ft of water on the return side of the pump will balance the discharge head developed from a height of 10 ft of water on the outlet side of the pump.

80.14 SPECIAL PIPING CONSIDERATIONS

Most gas furnaces are limited to return-water temperatures of 140°F or greater. This is because the low water temperature would bring the boiler flue gas temperature below its dew point. Condensation in the boiler flue gas would lead to corrosion in the heat exchanger. The return water is mixed with the supply water to achieve the desired return-water temperature.

System Bypass Piping

This type of system is used on single-zone systems or multiple-zone systems using zone control valves. Notice the circulator is located on the return piping (Figure 80-37). The bypass valve will mix supply water with the return water to ensure that the return-water temperature does not drop

Figure 80-37 System bypass arrangement.

too low. Typically, gas furnaces should not operate with return-water temperatures of less than 140°F. Plug valves offer good control to regulate the amount of flow that will be diverted to the return.

Pump-Away Bypass

The pump-away bypass is another method for controlling return-water temperature for a single-circulator pump system that is using zone control valves. The bypass is installed on the discharge side of the circulator, as shown in Figure 80-38. Hot-water flow regulated through this bypass is used to raise the temperature of the return water. The cost of installing this type of bypass is low, and the temperature can be easily set with a contact thermometer.

Pumped Bypass

For systems with multiple zones and circulators, a dedicated bypass circulator provides a strong blending flow without reducing the flow to any other heating zone. A typical common circulator can be used for this purpose (Figure 80-39).

80.15 HOT-WATER HEATING APPLICATIONS

It is common for oil-fired boilers to be installed to accommodate both heating and domestic hot-water service. Coil-type heat exchangers can be located directly within the boiler, or a separate circuit is installed for an indirect-fired hot-water heater. More recently, solar heating systems are being used to supplement the hot-water demand and are not only becoming more common but are required for new construction in some localities. These circulate either water or glycol from a hot-water holding tank through outdoor solar panels.

Figure 80-38 Pump-away bypass arrangement.

Figure 80-39 Pumped bypass arrangement.

Indirect-Fired Hot-Water Heaters

Hot-water heating systems can be configured to also supply domestic hot water. A separate hot circulating loop is delivered to an indirect-fired hot-water heater. The heater acts as a storage tank and will have a coil-type heat exchanger located inside that is supplied with hot water from the boiler (Figure 80-40). This type of hot-water heater will have separate controls to maintain the domestic water at the setpoint temperature and a relief valve (Figure 80-41). The tank will need to be large enough to deliver an average supply of hot water based upon the household size. A drawback with this type of system is the amount time required to replenish the

Figure 80-40 Heating coil located inside an indirect-fired hot-water heater.

Figure 80-41 Indirect-fired hot-water heater showing the temperature control and the relief valve.

hot water. Hot water being used for multiple uses at the same time, such as washing clothes while taking showers, may lead to a temporary drop in water temperature.

UNIT 80—SUMMARY

Hydronic heating systems require circulator pumps and piping loops for delivering hot water from a boiler to a terminal unit. The different types of terminal units include baseboard heaters, convectors, fan coil units, and radiators. Radiant floor heating is another popular application of

a hydronic system. There are a number of different types of piping arrangements, such as series loops, one-pipe venturi systems, two-pipe systems, and zoned systems. These systems also require expansion tanks, and many systems also require balancing valves, mixing valves, and motorized control valves. Most hot-water heating systems do not come as packages and must be installed individually based upon the building floor plan and heating requirements.

WORK ORDERS

Service Ticket 8001

Customer Complaint: No Heat on Second Floor

Equipment Type: Gas-Fired Boiler with Forced Hot Water—Two Zones

The technician arrives at a no-heat call and speaks with the customer. The boiler appears to be running fine, but there is no heat on the second floor. The technician first checks the thermostat and finds that it is calling for heat as it should, but the circulator for the zone is not operating. The motor circuit is tested with a multimeter for voltage, and there is 120 V. The power is disconnected from the circuit, and the circulator motor electrical leads measure infinite resistance, indicating an open in the winding. The circulator is replaced as a unit and electrically wired. When the power is turned back on, the circulator begins running as normal.

Service Ticket 8002

Customer Complaint: One Room Too Cold

Equipment Type: Radiant Floor Heating System

The technician meets with the customer, who explains that a newly installed radiant floor heating system works well except for in the bedroom. The system is an under-floor system, and all of the floors are tile except for the bedroom, which has a thick wall-to-wall carpet. The technician locates the supply manifold for the individual circuits and notes that the water temperature is mixed to be about 110°F. The technician adjusts the mixing valve for the bedroom to elevate the mixed temperature to 140°F. The technician tells the customer that it may take a few hours before any difference is noticed, but eventually the room should be warmer than it has been. The radiant heat temperature for the bedroom needed to be set slightly higher than the rest of the rooms because the wall-to-wall carpeting does not transfer the heat as well as the tile.

Service Ticket 8003

Customer Complaint: Banging Noise from Pipes

Equipment Type: Gas-Fired Boiler—Three-Zone Hot-Water Heating System

The customer tells the technician that the system was fine until the heat was recently turned on to the upstairs

bedrooms. Ever since that time, there has been an occasional banging in the pipes. The upstairs heat had been turned off to conserve energy, and now that company has arrived it is back on again. The technician suspects that the water from the second floor has drained back to the boiler through a faulty check valve, allowing air to enter the system. The technician turns up all the thermostats so that all of the circulators will be running and then goes to each baseboard unit and vents air from each vent. After all the air is vented from the system, there seems to be no more knocking noise.

The technician tells the customer that the system will need to be shut off and drained to replace the check valve. The check valve may have just had something stuck underneath its seat and may not need replacement. The technician recommends leaving the check valve alone for now and replacing it when the heating season is over if the banging noise returns.

UNIT 80—REVIEW QUESTIONS

1. Define *hydronics*.
2. What was the common choice for hydronic piping in the past, and how is that changing?
3. What are the advantages of hot-water heating systems based on overall comfort?
4. What are the disadvantages of hot-water heating systems?
5. What safety measures are used to allow for expansion in a hot-water heating system?
6. What provisions should be made to prevent water from freezing during low-temperature periods of operation for a hydronic heating system?
7. Why is it important when working on electrical components such as pump motors to make sure that all of the water in the system has been removed?
8. List the different types of terminal units used for hot-water heating systems.
9. How does a fan coil unit differ from a convector?
10. What are the advantages of radiant floor heating?
11. Describe a series loop, single-circuit hot-water piping system.
12. What is the purpose of the venturi on a one-pipe venturi system, single circuit?
13. What is the advantage to a two-pipe system, direct return?
14. How does a two-pipe system, reverse return, differ from a two-pipe system, direct return?
15. How is hot water controlled to a zone?
16. How is the water returned from a zone to the boiler?
17. How does a motorized zone control valve work?
18. What are mixing valves used for?
19. Why might mixing valves be used for radiant floor heating?
20. How does a radiant floor heating system transfer heat?
21. How does an open piping system differ from a closed-type piping system?

UNIT 81

Boilers and Related Equipment

OBJECTIVES

After completing this unit, you will be able to:

1. explain the difference between steam boilers and hot-water boilers.
2. list the working pressures and temperatures for low-pressure, medium-pressure, and high-pressure boilers.
3. list the accessories required for a hot-water boiler.
4. vent air from a hot-water boiler.

81.1 INTRODUCTION

All boilers are used to heat water. Where hot water is used to transfer heat, the output of the boiler maintains a temperature below the steaming temperature. At sea level atmospheric pressure, water boils at 212°F; at higher pressures the boiling point increases. Where large amounts of heat need to be transferred, the boiler is used to produce steam. This is because about 970 BTU/lb of heat can be added to water at 212°F and atmospheric pressure to change it into steam at the same temperature. This same amount of heat will be transferred to the air passing across a heating coil as the steam turns back into condensate.

In general, for residential and small commercial installations, hot-water boilers are used rather than steam due to the size of the installations and accuracy of control that can be provided.

81.2 BOILER CLASSIFICATIONS

Boilers are classified three ways: (1) working temperature/pressure, (2) fuel used, and (3) materials of construction.

Low-Pressure Boilers

Low-pressure boilers have a working pressure of up to 15 psi steam and/or up to 160 psi water pressure at a maximum of 250°F operating temperature. Low-pressure boilers are most commonly used for heating systems. Some are equipped with internal or external heat exchangers to supply domestic hot water. Residential heating boilers are gas- and oil-fired boilers with inputs less than 300,000 BTU/hr. Commercial heating boilers are those with heating inputs of 300,000 BTU/hr and larger. Water boilers are available from outputs of 50,000 BTU to 50,000,000 BTU (50 MBH). Every steam and hot-water boiler is rated at a maximum working pressure determined by the ASME code under which it is constructed and tested. A typical nameplate rating for a low-pressure hot-water boiler is shown in Figure 81-1. The boiler is rated for a maximum allowable working pressure (MAWP) of 30 psi, a maximum water temperature of 250°F, and a relief valve capacity of 129 lb/hr.

Figure 81-1 Low-pressure residential hot-water boiler nameplate.

Medium- and High-Pressure Boilers

Medium- and high-pressure boilers operate above 15 psi steam and/or over 160 psi water pressure at temperatures above 250°F (Figure 81-2). Steam boilers are available for up to 50,000 lb/hr of steam. Many of them are used in central

Figure 81-2 Steam pressure gauge for a high-pressure boiler.

Figure 81-3 Central station high-pressure boilers.

station systems for heating medium and large commercial buildings that are beyond the range of a hot-water boiler (Figure 81-3). Often industrial boilers are used for the dual purposes of generating process steam and heating steam. As an example, the process steam may be used in a hospital for sterilizing surgical equipment, while the heating steam that is reduced to a lower pressure is used in the heating coils.

CAUTION

Boiler operators are licensed and regulated by local, state, and federal agencies. This typically applies to commercial boilers and boilers located in public buildings. Only individuals holding appropriate licenses may be operating engineers in charge of boilers. Domestic hot-water boilers are typically excluded from this category.

SAFETY TIP

All boilers must be routinely inspected and certified for operation. The boiler certification must be posted in plain view in the boiler room. This typically applies to commercial boilers and boilers located in public buildings. Domestic hot-water boilers are typically excluded from this category.

81.3 BOILER FUELS

Boilers may be designed to burn coal, wood, various grades of fuel oil, or various types of fuel gas or operate as electric boilers. Heat-recovery steam generators utilize the exhaust gas from a gas turbine to generate steam. Each fuel has its own special firing arrangement depending on the type of application.

By far the most common types of fuel for residential and light commercial applications are gas and oil. Natural

Figure 81-4 Gas-fired boiler.

gas is clean burning and convenient if it is readily available through a pipeline connection (Figure 81-4). The burner arrangement for a gas-fired hot-water boiler is very similar to a gas-fired hot-air furnace. Typically, the return-water temperature for a gas-fired hot-water boiler should not be below 140°F.

In rural areas where there is no gas pipeline connection, propane may be used, but this requires a storage tank and regular delivery. The propane storage tank will be located outside the building and will be subject to proper installation to meet local codes. A common alternative is the use of #2 heating oil (Figure 81-5). The oil storage tank may

Figure 81-5 #2 oil-fired high-pressure boiler with gas for initial igniter start.

Figure 81-6 Typical cast iron gas boiler.

be located within the building, typically in the basement. Similar to an oil-fired hot-air furnace, an oil-fired hot-water boiler will have a burner arrangement with an oil pump assembly.

81.4 MATERIALS OF CONSTRUCTION

Boilers must be designed to withstand high operating pressures and temperatures. It is important that the materials and methods of construction meet local and national codes. Many boilers are required to be constructed of materials in accordance with ASME (American Society of Mechanical Engineers) standards.

Cast Iron Boilers

Hot-water boilers are constructed using cast iron, steel, or stainless steel. A typical gas-fired cast iron boiler is shown in Figure 81-6. An oil-fired cast iron boiler is shown in Figure 81-7. Both of these boilers are assembled and shipped as packaged units. The package usually includes the circulator pump and complete controls. The wall thermostat is shipped separately for field mounting and wiring. Some packages also include a diaphragm-type expansion tank and a check valve piped into the unit. Cast iron boilers are constructed of individually cast sections assembled in groups or sections. Push or screw nipples or an external header join the sections together by applied pressure to seal them tight. This type of construction provides passages for water, steam, and products of combustion.

Figure 81-7 Typical packaged cast iron oil boiler with burner assembly not yet installed.

Figure 81-8 Steel boiler, gas fired.

Steel Boilers

A steel boiler is shown in Figure 81-8. This boiler is also shipped as a package with accessories and controls. Newer designs with condensing type heat exchangers produce efficiencies in the AFUE 90+ percent range. Condensing boilers have recently been developed to improve the efficiency of boilers. Previously, the flue gases were not allowed to condense in the boiler due to the corrosion that they could cause. These new condensing boilers are constructed with heat exchangers made of materials to resist corrosion.

Steel boilers are fabricated into one assembly of a given size, usually by welding. The heat exchangers for steel boilers can be fire tube or water tube design. The fire tube construction, which is most common, has flue gas passage space between the water holding sections. The water tube construction uses water-filled tubes for the heat exchanger

with the flue gases in contact with the external surface of the tubes.

The surface of steel boilers can be electroplated or clad with nickel or other corrosion-resistant material. Although this adds significant cost to the boiler, it significantly extends the unit operational life. Corrosion protection can also be provided by placing a sacrificial zinc rod in the tank. Zinc is more reactive than steel, so it corrodes away first and can be easily replaced when it is gone.

For larger hot-water installations, a high-efficiency pulse-type steel boiler is available, such as the examples shown in Figure 81-9. These boilers produce efficiencies as high as AFUE 96 percent. Both combustion air and gas metering valves are standard equipment. A small fan is used to deliver combustion air on start-up but shuts off after ignition. The unit is primarily controlled by a microprocessor.

Other Boiler Types

Copper boilers are usually some variation of the water tube type. The two most common tube types are parallel-finned copper tube coils with headers and serpentine copper tube units. Some are offered as residential wall-hung boilers. Electric boilers are in a separate class. No combustion takes place and no flue passages are needed. Electric elements can be immersed in the boiler water.

81.5 RESIDENTIAL HOT-WATER BOILERS

A boiler is a pressure vessel designed to transfer heat (produced by combustion or by electrical resistance) to a fluid, usually water. If the fluid being heated is air, the unit is called a furnace. If the fluid is water, then it is called a boiler. The heating surface of a boiler is the surface area with water on one side and the fire and exhaust gases on the other side. Boiler design provides for connections to a piping system that delivers heated fluid to the point of use and returns the fluid to the boiler.

Residential hot-water boilers are classified as low-pressure boilers. A hot-water boiler typically heats water to a final temperature of 180°F to 200°F. The hot-water pump delivers this hot-water supply to terminal units in the heating circuit loop or to heating coils in an air handler. Water temperatures for most heating systems have a range of 130°F to 180°F, while radiant floor heating systems are much lower, at 85°F to 140°F. Too low a temperature will result in inadequate heating, while too high a temperature could be damaging to the piping or materials used in the heating loop. Because of this, there are different methods of mixing the supply and return water to achieve the desired supply temperatures.

The water will transfer its sensible heat in the terminal unit. The temperature difference from the supply to the return line is normally 20°F–40°F. In many boilers, the return water is mixed with the supply water to maintain a temperature of at least 140°F returning to the boiler to reduce the chance of reaching the dew point in the boiler flue gases.

81.6 RESIDENTIAL HOT-WATER BOILER PIPING DETAILS

A typical hot-water heating system diagram is shown in Figure 81-10. Key components include an oil- or gas-fired boiler, a circulation pump, an air separator, an expansion tank, radiant floor piping, a makeup water valve, a temperature/pressure-relief valve, and a backflow-prevention device required by code in many states. The piping arrangement for a wall-mounted gas-fired boiler hot-water heating system is shown in Figure 81-11.

Figure 81-10 Basic hydronic system: (a) oil-fired boiler; (b) circulation pump; (c) air separator; (d) expansion tank; (e) radiant floor piping; (F) makeup water valve; (G) temperature-pressure relief.

Figure 81-11 Piping arrangement for a hot-water heating system.

Figure 81-12 Compression-type expansion tank.

Expansion Tank

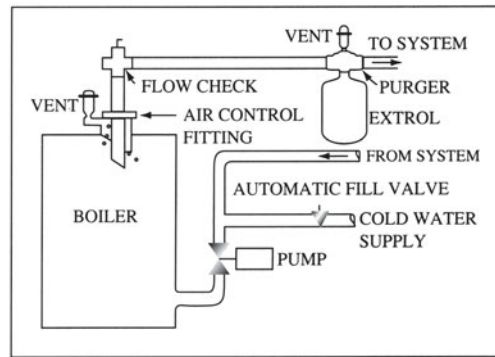

An expansion tank is placed in the piping to permit the expansion and contraction of the water volume. The tank holds both air and water. The air is compressed when the water volume expands, and the air expands when the water volume decreases. An open type of expansion tank is located above the highest terminal unit, usually in the attic, and has a gauge glass and overflow pipe to a drain. These are not very common today.

SERVICE TIP

After installing or working on an expansion tank, watch the boiler pressure as the boiler heats up. If the pressure rises too high, this could be due to an expansion tank sizing or operational problem.

Closed-type expansion tanks are welded gas tight and located above the boiler. The tank is partially filled with water to leave a cushion of air for expansion. Do not use an automatic air vent on this type of tank. The air will escape from the system rather than returning to the tank. Eventually the tank will waterlog. This type of tank should utilize a fitting that permits the air bubbles to rise directly into the tank but restricts the flow of water back into the tank, as shown in Figure 81-12.

Diaphragm-type expansion tanks are also welded gas tight but have a flexible rubber membrane between the air space and the water space that moves during operation to allow for the changing volume of water. The air is pre-charged (usually 12 psig for residential units) into the expansion tank and unlike the closed type does not come in contact with the water in the system. An automatic air vent should be installed on top of a diaphragm expansion tank, as shown in Figure 81-13. A recommended expansion tank location is shown in Figure 81-14.

(a)

(b)

(c)

Figure 81-13 (a) Diagram of a diaphragm-type expansion tank; (b) diaphragm expansion tank and automatic air vent; (c) cross-section of automatic air vent.

Figure 81-14 Recommended expansion tank hookup connected to discharge side of boiler.

SERVICE TIP

A weeping relief valve may be an indication of an expansion tank problem. If the tank is a closed type, it may be waterlogged. If the tank is a diaphragm type, the membrane may be damaged.

TECH TIP

To reduce the expense in piping for large water systems, steel pipe is used. However, steel pipe has the potential problem of rusting. To reduce the rust or corrosion problem, steel pipes are treated with a "pickling" solution. This treatment forms a barrier to rust formation in the pipe. In addition, chemicals are added to the water circulating through the system that further retard rust. Check with the chemical manufacturer for the proper mixing ratio.

Figure 81-15 Automatic purge valve located on top of residential boiler.

Figure 81-16 Water hammer arrester.

Air Removal and Water Hammer

Air must be eliminated from the piping system. Air vents need to be placed at high points of the system and on terminal units (Figure 81-15). Even if the system is free from air when filled, air can enter during normal operation. Air in the system can lead to noise and vibration similar to water hammer in the lines. Depending on the selection of accessories, air that collects during operation can be vented at the expansion tank. Some air remains in the expansion tank to act as a cushion for the expansion and contraction of water during temperature change.

Water hammer is a pressure surge or wave that is created when the water is forced to stop or change direction suddenly, such as quickly closing a valve. To reduce this effect, hammer arresters can be installed in lines where water hammer becomes a problem, particularly where there are sharp 90-degree bends (Figure 81-16).

Pressure-Relief Valves

The location of the pressure-relief valve is shown in Figure 81-17. The pressure-relief valve is usually set for 30 psig on a residential or small commercial system, and the piping

(a)

(b)

Figure 81-17 (a) Pressure-relief valve location; (b) manual lifting lever for pressure-relief valve.

Figure 81-18 Residential pressure-regulating valve for makeup water.

is arranged to discharge into an approved drain. The outlet must run to a safe place to eliminate the possibility of severe burns if the valve should lift. No shutoff valve can be installed between the relief valve and the boiler. The valve may be tested by lifting the lever located on its top. The valve lever should be operated at least once each year. Take precautions when lifting the valve to drain away and protect against burns from the hot water. If no water comes out, then the valve must be replaced. It is recommended that the valve be physically removed and inspected thoroughly at least once every 3 years.

Pressure-Regulating Valve

The boiler will need some makeup water from time to time. Typically, an automatic pressure valve supplied from the main building water line will be connected to the piping circuit (Figure 81-18). This will keep the system topped off with water. It is important to note, however, that minerals in water can build up on heat-transfer surfaces and cause overheating and eventual failure of cast iron sections. The water should fall between a 7.0 pH and an 8.5 pH with less than 7 grains hardness. Water treatment is recommended in areas where water quality is a problem.

Freeze Protection

If the conditions warrant, antifreeze can be circulated through the unit for layup periods. This should be thoroughly flushed prior to recommissioning the boiler. Use only approved solutions. Never use an automotive-type or RV-type antifreeze. An alternative to using antifreeze is to thoroughly drain the entire system of water. A drain valve will be located on the bottom of the boiler.

Figure 81-19 Energy manager control module.

81.7 RESIDENTIAL HOT-WATER BOILER CONTROLS

If a package boiler is used, the temperature- and pressure-limiting devices are supplied with the package; otherwise they must be applied during installation. There are a number of ways that residential or small commercial hot-water heating systems can be controlled, such as by thermostat, aquastat, manual reset high limit, and low-water cutout. Some residential boilers now come with an electronic control module for supervising most boiler functions (Figures 81-19 & 81-20).

STANDARD MANAGER DIP SWITCHES		EXPANDED MANAGER DIP SWITCHES	
		NOTE: "ON" is DOWN position	
Switch	Description	Function (OFF is UP, ON is DOWN)	
1	Return Low Temp	OFF = 120° / 140° F. (Oil) ON = 130° / 150° F. (Gas)

Monitor Light ON, 130F Flash		Excessive temperature alarm	
Monitor Light ON, 140F Flash		Burner or boiler circulation not functioning	

Figure 81-20 Electronic control system settings for residential boiler.

Thermostat

The thermostat signal is typically used to start the circulator pump. As the water begins to circulate, the boiler water temperature begins to drop and an aquastat signal fires the boiler based on boiler water temperature. Thermostat signals can also be used to open zone control valves. Motorized zone control valves open slowly while sending a signal to start the circulator pump. Some thermostat arrangements are configured to control both the fuel-burning device and the circulating pump. The advantage of this arrangement is that in mild weather the boiler water temperature is lower due to the shorter running time, producing more efficient operation.

Aquastat

An aquastat can be used to maintain boiler water temperature by controlling boiler firing. A single aquastat has one sensor typically located in the return-water line. A dual aquastat has sensors in both the supply and return lines and is often used for step firing control. A high-limit aquastat is used for a safety control only. A reverse-acting aquastat is sometimes used on a single-zone system (Figure 81-21). It will not allow the circulator to start until the boiler has reached its operating temperature.

High Temperature Limit

This is a safety control to shut the boiler down if the temperature becomes too high (Figure 81-22). This is usually above 200°F. The limit is normally reset manually.

Low-Water Cutout

If the water level in the boiler is low, a serious condition could result. If a boiler runs low on water, it can overheat,

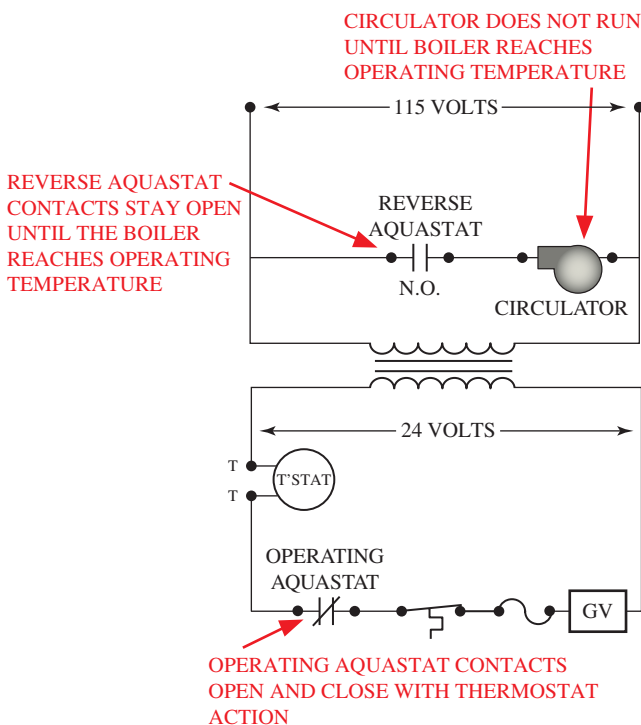

Figure 81-21 Reverse-acting aquastat.

Figure 81-22 High temperature limit.

CAUTION

It is extremely important that boilers not be allowed to run low or out of water, as they can shut down or implode as violently as if it exploded. Implosion comes from the rapid condensing of steam into water, creating a negative pressure in the boiler.

causing damage to the boiler. If a boiler runs out of water, it can explode as a result of steam pressure. The low-water cutout will automatically shut off the boiler on a low water level.

81.8 STEAM-HEATING BOILERS

Steam-heating boilers are most often used for commercial and industrial applications rather than residential use. Large buildings may use steam heat rather than hot water or a combination of the two. Hospitals, universities, and manufacturing facilities often have steam-heating boilers (Figure 81-23).

Figure 81-23 Oil-fired high-pressure steam-heating boiler.

Figure 81-24 Boiler steam safety valves vent to the outside of the building.

Steam heat reduces the total number of circulating pumps required. The steam will flow from the boiler to the heating coils located in the air handlers without needing to be pumped. However, a steam boiler will require different piping materials, relief valves, and control systems as compared to a hot-water boiler. The requirements are more stringent, and these types of boilers often require operators to obtain a boiler license.

Steam Boiler Safety Valves

Steam released from a ruptured pipe will expand rapidly depending on the operating pressure. If a high-pressure steam pipe on a boiler were to burst, the entire space would quickly fill with steam and possibly suffocate anyone present. This is why steam boilers utilize safety valves that vent outside of the building (Figure 81-24). The boiler safety valve will be set to open and relieve the steam pressure well before the burst pressure of any of the piping materials or boiler internals is reached (Figure 81-25).

Steam Boiler Controls

Instead of controlling water temperature, steam boiler controls regulate the steam pressure. The burner is either fired on and off to maintain a constant steam pressure or modulated between higher and lower firing rates. Most automated steam boilers have modulating burners that automatically adjust the air and fuel flow to meet the steam demand. The water level in the boiler remains constant and is controlled by a feed-water regulator. Commercial and industrial steam-heating boilers will have a water level indicator, steam pressure gauges, switches, and modulating controls (Figure 81-26).

Figure 81-25 Boiler steam safety valve with manual release lever.

Figure 81-27 Ball-type mechanical float trap.

Steam Traps

Steam traps located in steam-return lines drain condensate from the lines without allowing the steam to escape. Maximum efficiency of a steam-heating coil occurs only when condensate leaves the coil, not steam. If steam leaves the heating coil, then its useful latent heat will be wasted.

There are many different kinds of steam traps. They all consist essentially of a valve and some device or arrangement that will cause the valve to open and close as necessary to drain the condensate without allowing the escape of steam. Common steam traps include the mechanical ball-float and the thermostatic bellows types.

A mechanical ball-float steam trap is shown in Figure 81-27. The valve of the trap is connected in such a way that the valve opens when the float rises. When the steam leaving the heating coil begins to condense, the resulting water level rises and lifts the float, allowing the valve to open. The condensate drains out and the float lowers to close the valve until more steam condenses. The float does not necessarily need to have the shape of a ball (Figure 81-28).

A thermostatic bellows steam trap is shown in Figure 81-29. It has fewer moving parts as compared to a mechanical-type steam trap. The valve for the trap is

Figure 81-28 Mechanical float trap.

Figure 81-29 Cutaway of a thermostatic bellows steam trap.

attached to the bellows in such a way that the valve closes when the bellows expands. Steam enters the trap body and heats the volatile liquid contained inside the sealed bellows. This causes the bellows to expand and close the valve. As the steam cools and condenses, the bellows contracts to open the valve, and this action allows the condensate to drain.

Y-type strainers are located in steam systems to collect scale and rust that travels along with the steam (Figure 81-30). This protects valves and traps from becoming plugged up. Periodically the y-strainers should be isolated, the pressure allowed to drain, and the strainer removed and cleaned.

Figure 81-30a Cutaway of a y-type steam strainer.

Figure 81-30b Cutaway of a y-type steam strainer and thermostatic trap.

UNIT 81—SUMMARY

Most boilers used for residential and light commercial applications are low-pressure hot-water systems. The firing arrangements are typically oil or gas and the burner assemblies are similar to those used in hot-air furnaces. The firebox, however, is surrounded by water and therefore takes on a different construction. The boiler can be directly controlled by a thermostat. More commonly, aquastats are used, which fire the furnace dependent on water temperature. Routine maintenance should include a test of the low-water cutout and the boiler pressure-relief valve.

WORK ORDERS

Service Ticket 8101

Customer Complaint: Routine Service

Equipment Type: Oil-Fired Residential Hot-Water Boiler

The technician is performing an annual maintenance call on an oil-fired hot-water boiler. The fuel filters are replaced and also the burner nozzle. The furnace flue gas passages are cleaned out with a vacuum. Before the boiler is started for a test run, the technician connects a short piece of hose from the outlet of the relief valve piping to a drain and lifts the relief valve manually. No water comes from the relief valve. The technician closes the isolation valves on the boiler, shuts off the automatic water supply, and opens the drain valve to release some of the water from the boiler. The relief valve is removed and replaced with a new one. Water is added back to the boiler while air is vented out and the automatic makeup valve is placed back into service.

Before starting the boiler, the new relief valve is tested and it releases water. The boiler is started and comes up to temperature normally. The relief valve is once again manually lifted and it drains water and closes tight when the lever is released.

Service Ticket 8102

Customer Complaint: Routine Service

Equipment Type: Gas-Fired Residential Hot-Water Boiler

The technician is conducting an annual maintenance call on a gas-fired hot-water boiler. The boiler pressure-relief valve drain piping has a trickle of water slowly coming from it. The technician checks the air pressure in the diaphragm expansion tank and it is zero. A small hand pump is connected to the fitting on the expansion tank, but it will not hold any pressure. The technician isolates that section of the piping system and replaces the expansion tank. After the installation, the system is vented for air. The technician lifts the pressure-relief valve by hand to see whether it will close tightly, and it does.

Service Ticket 8103

Customer Complaint: Not Enough Heat

Equipment Type: Gas-Fired Residential Hot-Water Boiler

The customer complains that the thermostat setpoint temperature is not being reached. The circulator pumps are running a majority of the time, but the baseboards still seem cold to the touch. The technician checks the pressure and temperature gauge on the furnace, and both are too low. The technician starts the boiler manually by placing a jumper around the aquastat. The boiler starts and the water temperature begins to rise. The combustion flame looks good. The technician shuts the boiler down and replaces the aquastat. The boiler is re-started, and now it runs normally.

UNIT 81—REVIEW QUESTIONS

1. When would a steam boiler be preferable over a hot-water-type boiler?
2. What water temperatures do most hot-water boilers heat up to?
3. What water temperature do radiant floor heating systems typically operate at?
4. What is the typical return-water temperature for a gas-fired boiler?
5. What is the working pressure for a low-pressure boiler?
6. What is the heating input for a low-pressure residential boiler?
7. What is the working pressure for medium- and high-pressure boilers?

8. What materials are boilers commonly made from?
9. What are some of the accessories required for a hot-water boiler?
10. What can be done to treat steel piping to help keep it from rusting?
11. Where should air vents be located in a hot-water heating system?
12. Why is it recommended to never put an air vent on a closed-type expansion tank?
13. What is a diaphragm type of expansion tank?
14. What could be the cause of a weeping relief valve on a hot-water boiler?
15. What can happen if a boiler runs out of water?
16. What pressure is the relief valve typically set at on a residential or small commercial system?
17. Can a hot-water boiler pressure-relief valve be tested?
18. What is the function of an aquastat?
19. What is a low-water cutout?
20. Where do high-pressure steam safety valves vent to?

UNIT 82

Cooling Towers

OBJECTIVES

After completing this unit, you will be able to:

1. explain the difference between mechanical- and atmospheric-draft cooling towers.
2. list the different types of mechanical-draft cooling towers.
3. explain how cooling towers lower the water temperature below ambient.
4. list the common terms associated with cooling tower operation.
5. describe the piping arrangements used for cooling towers.
6. perform routine maintenance on a cooling tower.
7. explain how an evaporative condenser operates.

82.1 INTRODUCTION

The cost and scarcity of water (unless drawn from a lake or wells and returned) has become prohibitive and is even outlawed for refrigeration and air conditioning use by some local city codes. Ordinances often restrict the use of water to the point where such installations are forced to use all air-cooled equipment, water-saving devices such as the evaporative condenser, or a water tower.

Cooling towers are an essential part of most central station air-conditioning systems. For the smaller systems, even up to 100 tons, there has been a trend toward the use of remote air-cooled condensers. Their use is limited, however, to installations where the length of the refrigerant piping can be short enough to be practical. Almost all large condensing units and large packaged chiller units use water-cooled condensers with cooling towers.

A cooling tower is a large evaporative cooler that is used to reject heat from water. They are used with water-cooled condensers to cool the warm water leaving the condenser and return it to the condenser ready to absorb more heat. Cooling towers can be either open loop or closed loop. The water circulating in an open-loop system is also the water circulating through the condenser. Closed-loop systems use a heat exchanger to separate the water in the condenser loop from the water in the tower. That way only the tower water is exposed to the air. Closed-loop systems reduce the amount of water maintenance required for the water in the condenser loop. Closing the loop reduces the opportunity for contaminants to be introduced into the condensing loop.

82.2 COOLING TOWERS

The function of the water tower is to pick up the heat rejected by the water flowing through the condenser and discharge it into the air passing through the tower. The cooling tower delivers the condenser water supply at about 85°F, pumped by the condenser pump, to the water-cooled condenser on the water chiller. The condenser water is warmed

by the rejected heat from the chiller to about 95°F and returned through the condenser water return to the cooling tower, where it is cooled by heat transfer to the airstream and evaporation.

Figure 82-1 is a schematic drawing showing the principle of operation used by a cooling tower. The water from the heat source is distributed over the wet deck surface (fill media) by spray nozzles. Air is simultaneously blown upward over the wet deck surface to absorb sensible heat from the water. In addition, a small portion of the water will evaporate, which removes latent heat from the remaining water. The cooled water is collected in the tower sump and pumped back to the condenser.

82.3 MECHANICAL-DRAFT COOLING TOWERS

A mechanical-draft tower utilizes a motor-driven fan to move air through the tower, the fan being an integral part of the tower. A typical mechanical-draft cooling water tower is shown in Figure 82-2. They are available in many configurations and arrangements. The smallest cooling towers are structured for only a few gallons of water per minute, while the largest cooling towers may handle upwards of thousands of gallons per minute.

Induced-Draft and Forced-Draft Cooling Towers

Mechanical-draft towers are categorized as either being induced draft or forced draft. An induced-draft tower has the fan located in the airstream leaving the tower and draws the air through it (Figure 82-3). A forced-draft tower has the fan located in the airstream entering the tower and blows the air through the tower.

The type of tower installed is dependent on location and application. The fan static discharge pressure will be higher for a forced-draft tower as compared to an induced-draft tower. A crossflow tower can be configured so that

Figure 82-1 Schematic view of cooling tower construction.

the height is reduced compared to a counterflow cooling tower. It will be shorter but wider. Crossflow cooling towers are also sometimes used for indoor applications. Two connections to the outside are required. One connection is for drawing outdoor air into the tower and another is for sending it back outside again.

Counterflow Cooling Towers

An induced-draft counterflow cooling tower is shown in Figure 82-4. The air and water flow in opposite directions in a counterflow design. Typically, the water enters the tower

(a)

(b)

Figure 82-2 (a) Air inlet on a mechanical-induced-draft crossflow cooling water tower; (b) water inlet and outlet piping.

Figure 82-3 Fan blades and grille located on top of induced-draft cooling tower.

Figure 82-6 Water-distribution spray nozzles located on the top of the tower.

Figure 82-4 Induced-draft counterflow cooling tower.

at the top through a distribution header (Figure 82-5). The water is sprayed through nozzles in the form of a shower either by pump pressure or by gravity pressure from the water-filled headers (Figure 82-6). The hot water flows from the header into the tower fill material. This material is usually constructed of plastic or wood shells. The fill is much like a honeycomb found in a bee's nest and slows the fall of the water and increases its surface exposure (Figure 82-7). The fan pulls air through the fill. This air passes over and directly contacts the water to transfer heat from the warm water into the air. The cooled water falls to collect in the lower basin of the tower. A wet sump has the basin located

Figure 82-5 Water is pumped to the top of the tower.

(a)

(b)

Figure 82-7 (a) Plastic honeycomb fill; (b) support bracing for fill looking down from the top of the tower.

(a)

(b)

(c)

Figure 82-8 (a) Wet cooling tower sump; (b) dry cooling water sump; (c) cooling water piping to the dry basin sump.

inside the tower, while a dry sump has the basin located underneath (Figure 82-8). The water is then pumped back to the water-cooled condenser to absorb more heat from the refrigerant.

Crossflow Cooling Towers

A slightly different arrangement is shown in the induced-draft crossflow cooling tower shown in Figure 82-9. The air is drawn across the cooling water rather than up through it. Forced-draft towers are arranged so that the air is blown through rather than drawn through the fill material. Whether the air is drawn through or blown

Figure 82-9 Induced-draft crossflow cooling tower.

through, the basic configurations are still similar in design. Figure 82-10 shows a forced-draft counterflow cooling tower, while Figure 82-11 shows a forced-draft crossflow cooling tower.

Figure 82-10 Forced-draft counterflow cooling tower.

Figure 82-11 Forced-draft crossflow cooling tower.

TECH TIP

The visible cloud, called the plume, that exits cooling towers during cool, damp weather can be a problem in some circumstances. Airports, for example, cannot have large plumes of water vapor rising that might interfere with control tower visibility at the airfield. Plume-suppression kits are available. These kits draw in additional air and disperse the plume in a turbulent draft caused by the suppression fans. Even though some plume may be visible a few feet above the tower, the plume does not extend hundreds of feet in the air, as is the case with an unsuppressed plume.

82.4 ATMOSPHERIC (NATURAL) DRAFT COOLING TOWERS

An atmospheric-draft cooling tower is also referred to as a hyperbolic “natural”-draft cooling tower (Figure 82-12). Natural-draft cooling towers rely on prevailing winds and convection currents to move air across the wetted media in the tower. Natural-draft towers are normally larger than mechanical-draft towers for the same capacity. A properly sized natural-draft tower normally has a low operating cost since no power is used to move air.

This type of tower has no fill material or fan and depends on the spray nozzles to break up the water into a spray. Airflow through this tower is produced by natural circulation due to the density difference between the heated air in the tower and the cooler outside air. In comparison to mechanical-draft towers, the size, weight, and location requirements of an atmospheric-draft cooling tower reduce its use considerably. They are more often used for large electrical power stations and are seldom encountered in refrigeration service work.

Figure 82-12 Atmospheric-draft cooling tower.

82.5 EFFECT OF WET-BULB TEMPERATURE ON TOWER OPERATION

A cooling tower evaporates a portion of the water stream to cool down the remaining water. Drier air will allow more water to evaporate and increase the cooling tower efficiency as compared to humid air. Therefore, one of the most significant factors in cooling tower performance is the outdoor wet-bulb temperature, which provides an indication of how humid or dry the air is.

Sensible Heat Transfer

When the air in the cooling tower comes into contact with the water, the air absorbs sensible heat and becomes hotter and the water rejects sensible heat and becomes cooler. When the air temperature and the water temperature are equal, no more sensible heat transfer takes place. On a day when the outside dry-bulb temperature is higher and the air is hotter, less sensible heat transfer will take place. To adjust for higher outside dry-bulb temperatures, the water flow, the airflow, or a combination of both will need to be increased.

Latent Heat Transfer

The primary cooling of the circulating water is provided by latent heat of evaporation. Each pound of water evaporated by the cooling tower removes 970 BTU of latent heat. At that rate, it takes about 12 lb of water being evaporated to remove each ton of heat from the circulating water: $12,000 \text{ BTU/ton} \div 970 \text{ BTU/lb} = 12.3 \text{ lb of water}$. This amounts to approximately 1.5 gallons per hour. Compared to 1.5 gallons per minute for wastewater systems, it is easy to see that cooling towers save water.

Another outside air condition other than dry-bulb temperature that affects cooling tower performance is the outside humidity. If the relative humidity is low, then some of the water passing through the cooling tower will evaporate. Any water that evaporates (phase change, which may be called a change of state) will require the addition of latent heat. Some of this heat will come from the water that does not evaporate. As some of the water evaporates, the remaining water becomes cooler. In this way the water is not only cooled by the sensible transfer of heat to the air but also by the latent heat transfer due to evaporation.

Wet-Bulb Temperature

Cooling towers cool the circulated water through evaporation by spraying water through a moving airstream. In a typical tower, water “rains” down while air is pulled through the water spray using a fan. The middle of the tower is filled with wetted media to increase the surface area of the water exposed to the air. The fill increases the exposure of the water to the air and increases evaporation.

Cooling tower performance is governed by the entering-air wet-bulb temperature. Dry air has a lower wet-bulb temperature than wet air because the rapid evaporation of water cools the sock on the wet-bulb thermometer. Dry air can more easily evaporate water, so cooling tower capacity is highest with dry air. Nominal tower capacities are sized

to cool the incoming water 10°F, from 95°F to 85°F with an outdoor wet-bulb temperature of 78°F.

A wet-bulb thermometer is an ordinary dry-bulb thermometer with a wetted cotton wick. As water from the wick evaporates, latent heat is removed from the thermometer, lowering its temperature. At a lower relative humidity, more water evaporates from the bulb and gives a greater difference between wet-bulb and dry-bulb readings. This means the drier the air, the more water will evaporate and the wet-bulb temperature will be lower.

It follows, then, that cooling tower operation does not depend solely on the dry-bulb temperature. The ability of a cooling tower to cool water is a measure of how close the tower can bring the water temperature to the wet-bulb temperature of the surrounding air. The lower the ambient wet-bulb temperature, the lower the tower can cool the water. It is important to remember that no cooling tower can ever cool water below the wet-bulb temperature of the incoming air. In actual practice, the final water temperature will always be at least a few degrees above the wet-bulb design temperature.

82.6 COOLING RANGE, APPROACH, AND HEAT LOAD

The following terms and definitions apply to all cooling towers and are illustrated in Figure 82-13.

- **Cooling range** The number of degrees Fahrenheit through which the water is cooled in the tower. It is the temperature difference between the hot water entering the tower and the cold water leaving the tower.
- **Approach** The difference in degrees Fahrenheit between the temperature of the cold water leaving the cooling tower and the wet-bulb temperature of the air entering the tower.
- **Heat load** The amount of heat “thrown away” by the cooling tower in BTU per hour. It is equal to the pounds of water circulated multiplied by the cooling range.

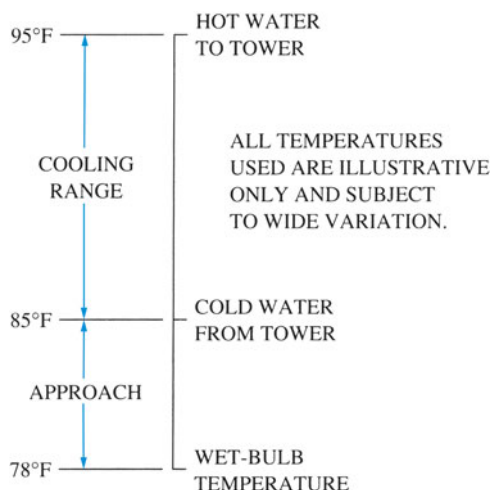

Figure 82-13 Range and approach as applied to cooling tower selection.

EXAMPLE 82-1: SOLVING FOR COOLING TOWER CAPACITY

Given a tower circulating 18 gpm with a 10°F cooling range, what would be the capacity?

Use the following formula:

$$Q = \text{gpm} \times 500 \times \text{TD}$$

where

Q = heat rejection in BTU/hr

gpm = flow in gallons per minute

500 = factor derived from specific heat of water
(1) \times 60 min/hr \times 8.33 lb/gal

TD = temperature difference in °F

Therefore,

$$\begin{aligned} Q &= 18 \text{ gpm} \times 500 \times 10 \text{ F} \\ &= 90,000 \text{ BTU/hr} \end{aligned}$$

82.7 DRIFT, EVAPORATION, BLOWDOWN, AND MAKEUP

Some of the water that evaporates from a cooling tower will be carried away by the air, and this is called drift. The amount of water lost will vary with the size of the cooling tower. Under certain ambient conditions, large cooling towers can produce a large white plume of water vapor that looks similar to fog.

Drift

Drift is the small amount of water lost in the form of fine droplets carried away by the circulating air, as shown in Figure 82-14. It is independent of, and in addition to, evaporation loss. For mechanical cooling towers, this will range from 0.1 to 0.3 percent of the total water being cooled.

Figure 82-14 Drift can be seen rising out of this cooling tower on a hot, humid summer day.

Evaporation

Theoretically, the evaporation rate is 1 percent of the water supplied to the tower for every 10°F the water is cooled.

Blowdown

The drift and evaporation of the water in the cooling circuit will leave solids behind, depending on the quality of the water. Blowdown (sometimes called bleed-off) is the continuous or intermittent draining of a small fraction of circulating water to prevent the buildup and concentration of scale-forming minerals and other nonvolatile impurities in the water.

Makeup

Makeup is the water required to replace water lost by evaporation, drift, and blowdown.

TECH TIP

Algae and slime are also present in the cooling water circuit and must be controlled chemically. It is also important that cooling towers be treated with the appropriate biocides to minimize the risk of *Legionella pneumophila* bacteria contaminating the tower.

82.8 CONTROLLING WATER-COOLED CONDENSER CAPACITY

The capacity of water-cooled systems using water towers can be affected by the outdoor temperature and humidity. It is possible for the cooling tower to cool so well that a minimum desired head pressure is not maintained. On water-cooled condenser systems, a temperature-controlled water valve that bypasses the tower and mixes cooling tower water with condenser water can be used. With this arrangement, the desired condenser water temperature

Figure 82-15 A mixing valve mixes hot and cold water from the condenser with cold water from the cooling tower to keep the returning water from being too cold.

can be maintained (Figure 82-15). The temperature-sensing element for the bypass valve is placed at the water entrance to the condenser.

82.9 COOLING TOWER PIPING CONNECTIONS

Figure 82-16 represents a typical mechanical-draft tower piping arrangement to the condenser of a packaged refrigeration or air-conditioning unit. Water supply lines should be as short as conditions permit. Standard-weight steel pipe (galvanized), type L copper tubing, and CPVC plastic pipe are among the satisfactory materials, subject to job conditions and local codes. The entire piping circuit should be analyzed to establish the proper location of valves for operation and maintenance of the system. A means of adjusting water flow is desirable. Shutoff valves should be placed so that each piece of equipment can be isolated for maintenance.

Cooling tower pump head is the pressure required to lift the returning warm water from the cold-water basin operating level to the top of the tower and force it through

Figure 82-16 Piping diagram for a system using water-cooled condenser and cooling tower.

the distribution system spray nozzles. This information is found in the manufacturer's specifications and is usually expressed in feet of head (1 psi = 2.31 ft of head).

SERVICE TIP

In areas that have a great deal of dissolved minerals in the water, extensive buildup of scale can be controlled by putting approximately 10 percent additional makeup water in the cooling tower so that the extra water is flushed down through the basin overflow. This will significantly increase the time intervals between descaling.

There are many types of pumps from which to choose. For most air-conditioning applications, an iron-body, bronze-fitted, end-suction, centrifugal pump with mechanical seals will do the job. Close-coupled 3,500-rpm pumps are economical and do not have to be aligned. If continuity of service is important, install a standby pump. By locating the condenser pump outdoors below the tower, a leaking seal will be less of a problem. For some applications, 1,750-rpm base-mounted pumps are specified. Motor replacements are easier, and the motors run quieter.

The installation of the pumps includes the following:

- The pump should be located between the tower and the refrigeration or air-conditioning unit so that the water is "pulled" from the tower and "pushed" through the condenser. It is good practice to place a flow control valve in the pump discharge line.
- The pump should be installed so that the pump suction level is lower than the water level in the cold-water basin of the tower. This ensures pump priming.
- If the pump is located indoors, consideration should be given to noise levels and water leakage should the seal fail.
- If an open, drip-proof motor is used outdoors, a rain cover will provide additional protection. Make sure ventilation is adequate so the motor does not overheat.
- The pump should be accessible for maintenance and installed to permit complete drainage for winter shutdown.

SERVICE TIP

When replacing motors that are frame mounted, it is very important that the alignment between motor and pump be accurate. Misalignment will cause noise and excessive bearing wear. Shims are available to make the alignment process easier.

82.10 COOLING TOWER WIRING

The wiring and control arrangement will vary depending on the size of the equipment being installed. In every case, the objective is to provide the specified results with

optimum operating economy and protection to the equipment involved.

For small refrigeration and air-conditioning systems, the ideal arrangement is based on a start-up sequence beginning with the cooling tower pump. The starter controlling the fan and pump will activate the compressor motor starter through an interlock. This method, illustrated in Figure 82-17, ensures sufficient condenser water flow so that compressor short-cycling is eliminated in the event of pump motor failure. In other words, the compressor cannot run unless the tower is operating. The tower fan is wired to allow cycling by a tower thermostat to maintain the proper condenser water supply temperature.

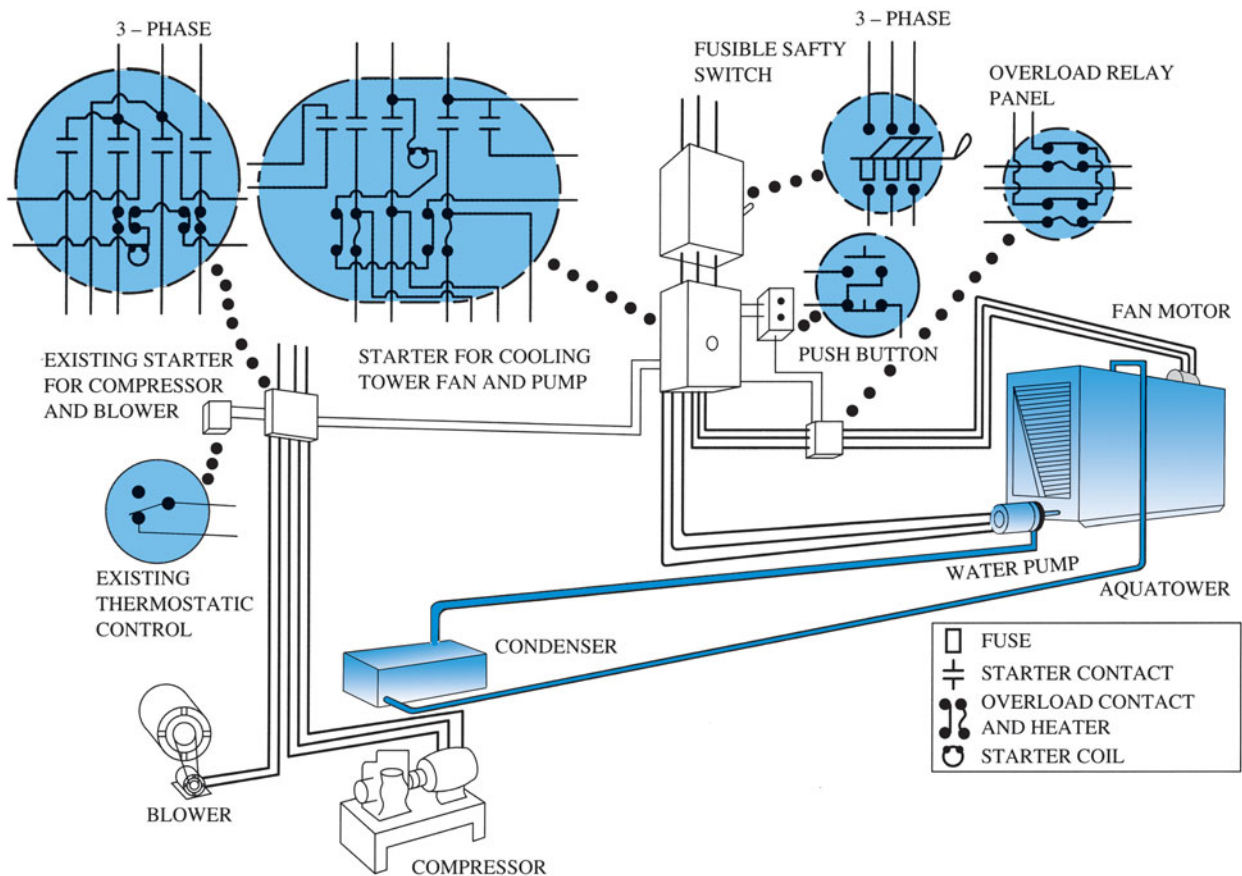

There are other, more economical methods based on using the compressor starter to activate the pump and fan, but water-temperature or flow-sensing devices should be incorporated as protection for the compressor. Where multiple refrigeration units are used on a common tower, the first unit that is turned on activates the cooling tower.

82.11 PROTECTIVE MEASURES FOR COOLING TOWERS IN COLD WEATHER

Winter operation or low ambient operation of a cooling tower is subject to special treatment for temperatures near freezing. Excessively cold water exiting the tower may cause thermal shock to the condenser and result in a very low condensing temperature. Cooling towers can also freeze during very cold weather. With enough heat load, the water in the tower will not freeze. Freezing is more likely to occur when operating at reduced load in cold weather. Ice accumulation on towers can add considerable weight to the tower, resulting in collapse of overloaded components.

One method of preventing the temperature of the water leaving the tower from falling too low is to turn off or reduce the speed of the tower fan. This will reduce the tower's thermal capability, causing the water temperature to rise. If this is not sufficient, a bypass valve can be placed in the tower piping to permit dumping warm water directly into the tower base, thus bypassing the spray or water-distribution system. A combination of both fan and total bypass may be needed to ensure leaving-water temperatures remain high enough during cold weather, but reducing the water flow will contribute to tower freeze-up. Sump heaters can be thermostatically controlled to keep the sump above 40°F. Prolonged operation at below-freezing conditions usually requires a total shutdown and draining of the tower sump and all exposed piping. Automatic thermostatically controlled drain-down solenoids can drain all the water out of the sump if the water temperature approaches freezing.

Antifreeze chemicals can be added to protect the condenser water loop in closed-loop towers during the winter, but it is not normally used in the tower water. The addition of antifreeze to the condenser water loop changes the specific heat value of the circulating water. The specific heat drops, requiring more water to be circulated to accomplish the same amount of heat removal.

NOTE: ACTUAL WIRING DIAGRAM FOR EQUIPMENT PURCHASED SHOULD BE OBTAINED FROM STARTER OR RELAY MANUFACTURER.

Figure 82-17 Typical wiring diagram for water-cooled condensing unit and cooling tower.

CAUTION

For a number of reasons, including environmental, expense, and maintenance, some cooling tower operators do not put antifreeze in their cooling towers. These towers are typically protected by either draining the towers in prolonged cold spells or running the circulator pumps. A significant disadvantage to this method is that a sudden cold spell may freeze the system before it can be drained. Also, power failure resulting from cold weather can stop the circulating pumps, which can result in a freeze-up.

A piping and control arrangement to provide winter operation is shown in Figure 82-18. This arrangement provides an inside sump. During normal operation, when the ambient temperature is above freezing, the water flows from the inside sump, through the condenser into the tower, and back to the sump. When the thermostat senses near-freezing water temperatures, the three-way valve is repositioned to direct the flow of water from the condenser directly to the inside sump, bypassing the tower. When there is no flow to the tower, the tower fan is cycled off.

82.12 COOLING TOWER MAINTENANCE

Proper maintenance is extremely important to keep a cooling tower operating at peak efficiency. Maintenance should include routine cleaning and chemical treatment to reduce mineral scale deposits, corrosion, bacteria growth, and fouling of the water.

Fans

Cooling tower fans are often belt driven (Figure 82-19). It is important to regularly check belt tension and wear. Vibration sensors will help to continuously monitor the fan condition and provide an early indication of problems. Existing fans can be equipped with vibration sensors that can be wired back to a continuous monitoring system (Figure 82-20).

Cooling Tower Cleaning

Peak performance of a water-cooled condenser and cooling tower system depends heavily on regular maintenance. Growths of slime or algae, which reduce heat transfer and clog the system, should be prevented. The success of any water treatment lies in starting it early and using it regularly. Once scale deposits have formed, it can be costly to remove them.

Figure 82-18 Winter operation using a cooling tower.

SERVICE TIP

The buildup of algae or other growth on water-cooled condensers can have the same adverse effect as debris on air-cooled condensers. It will reduce the system's operating efficiency. You must use a manufacturer-approved cleaning solution to remove these deposits. If the deposits are recurring, it may be necessary to use a water treatment to retard their growth.

In selecting condensers, application engineers will usually allow for the results of fouling so that the condenser

will have sufficient excess tube surface to maintain satisfactory performance during normal operation, with a reasonable period of service between cleanings. For conditions of extreme fouling and poor maintenance, higher fouling factors are used. Proper maintenance depends on the type of condenser; mechanical or chemical cleaning—or both—may be needed or employed to remove scale deposits.

(a)

(b)

(c)

Figure 82-20 (a) Vibration sensor attached to the top of the fan motor; (b) vibration sensor attached to the bottom of the fan motor; (c) the vibration sensors are wired to an interface unit .

The technician should become familiar with the companies, chemicals, and cleaning techniques recommended locally. Water treatment and maintenance can be expensive and time-consuming. Once commonly used compounds, chromates are no longer used. Chemicals used for treatment are increasingly becoming regulated. A treatment must be selected that complies with local regulations.

Cooling Tower Water Treatment

In addition to preventing scale, water treatment should protect the system components against corrosion. This is critical on systems using steel pipe. The water tower continuously aerates the water, adding oxygen. Open-circuit cooling tower loops are much more subject to corrosion than closed-circuit chilled- or hot-water systems.

In addition to chemical treatment, regular draining, cleaning, and flushing of the tower basin is recommended. Also, a blowdown valve should be adjusted to cause a small amount of overflow that trickles down the drain. This blowdown is the continuous or intermittent removal of a small amount of water (1 percent or less) from the system. Dissolved concentrates are continually diluted and flushed away.

SERVICE TIP

Cooling towers are protected with wire screens to prevent birds such as pigeons from roosting in the towers (Figure 82-21). However, even the best screening allows some birds access to the tower. Often towers become roosts for large flocks of pigeons during evening off hours. Unfortunately, when the tower is brought online in the morning, many of these birds drown. Their carcasses are washed into the basin. This organic material can cause the mineral deposits normally found in the basin during cleanup to become extremely nauseating. Better screening and more frequent basin cleanout will help reduce this problem.

82.13 EVAPORATIVE CONDENSERS

In an evaporative condenser, the hot-gas piping from the compressor discharge passes through the condenser like it does on an air-cooled condenser, except the tubes are

Figure 82-21 Wire screen for keeping birds out of the tower.

Figure 82-22 Evaporative condenser.

bare, and no fins are needed (Figure 82-22). In addition, the evaporative condenser has water nozzles that spray water over the tubes. As water flows over the hot tubes, it evaporates and picks up heat from the refrigerant, causing it to condense. At the same time, the blower in the evaporative condenser exhausts the humid, heat-laden air to the outside.

The evaporative condenser has a sump in the bottom with a float valve. As the water is evaporated, makeup water is added to the sump to replace it. Water from the sump is pumped to the spray nozzles at the top of the condenser and recirculated to provide continuous flow. When the water evaporates, it leaves a mineral residue in the sump that can accumulate. To prevent this, a continuous blowdown is provided. This residue also will adhere to the tubes and needs to be periodically cleaned off. If it accumulates on the tubes it will reduce the transfer rate. Water treatment is also recommended.

Evaporative condensers range in capacity from about 10 to 1,000 tons. They can be located inside or outside the building. If they are located inside the building, then outside air must be supplied. The heat-laden air they exhaust needs to be ducted to the outside of the building. They are more efficient than either the air-cooled or water-cooled condenser. This is because the capacity of cooling towers and evaporative condensers is governed by the lower wet-bulb temperatures, whereas air-cooled condensers are related to the higher ambient air dry-bulb temperatures. But of the three types, evaporative condensers are the least popular. Internal corrosion causes them to have the highest maintenance requirements. Their use is more frequent on industrial HVACR systems.

An interesting application of the evaporative condenser principle is included in the design of a room cooler. The condensed water vapor from the evaporator is directed to a small sump in the bottom of the condenser fan

housing. A slinger ring on the fan splashes this condensate onto the surface of the condenser coil. When this moisture evaporates from the surface of the hot condenser coil, it removes heat, similar to the action that takes place using an evaporative condenser. When the condensation is light or nonexistent, the condenser acts strictly as an air-cooled condenser.

UNIT 82—SUMMARY

Cooling towers allow the use of water-cooled condensers. They can also cool the water below the outside ambient dry-bulb temperature. Most cooling towers for HVACR systems are of the mechanical-draft type. The water used in a cooling water tower is circulated in a loop. It is important that it be treated to reduce slime, algae, *Legionella* bacteria, and scale buildup. A small measure of water is continually drained from the loop to reduce the buildup and concentration of scale-forming minerals. Makeup water is added to replace the water lost through evaporation, drift, and blowdown. Normal maintenance includes draining and cleaning the water basin, adding water treatment chemicals, and adjusting blowdown and makeup. System leaks or pumping problems should also be corrected. Proper cooling tower operation will result in cleaner condenser tubes and higher efficiency.

WORK ORDERS

Service Ticket 8201

Customer Complaint: Routine Service

Equipment Type: Rooftop Induced-Draft Cooling Tower

The technician finds the cooling tower on the rooftop and discovers that the water basin is very cloudy. The unit is shut down and the fans secured. The water basin is drained of water, and it is discovered that birds had found a way in and died in the basin. The technician cleans the basin and adds fresh water. The water is tested for pH and hardness, and it is within the limits. The correct amount of water treatment additive is put into the basin. The mesh screen surrounding the tower is repaired so that birds will not be able to find their way into the tower. The tower is then put back into service.

Service Ticket 8202

Customer Complaint: Compressor Tripped

Equipment Type: Central Air Conditioning with Mechanical Cooling Tower

The technician is told that the screw compressor for a water-cooled chiller was tripping on high-pressure cutout. The technician checks the condenser cooling

water inlet and outlet temperatures and finds them to be high. The condenser circulating pump pressure appears adequate and the pump seems to be operating normally. The technician next goes to the mechanical cooling tower. Only one of the two induced fans is operating. The power is secured and the fan motor circuit is tested and appears normal. Next the fan motor itself is tested and found to have a short. The fan motor is replaced and the tower put back into service.

Service Ticket 8203

Customer Complaint: Condenser Pressure High

Equipment Type: Central Air Conditioning with Mechanical Cooling Tower

The building superintendant tells the technician that the unit operating pressure has risen slowly over the past 6 months. This is also reflected in higher electricity bills for the complex. The cooling water to the condenser is wide open and therefore can be increased no more. The technician takes a water sample from the cooling tower and has it checked for hardness. It is above the recommended limits. The unit is shut down and drained. The condenser heads are taken off from each end to expose the tubes. A mechanical cleaner is used to pass through each tube and remove the scale buildup. After cleaning is complete, the condenser is put back together and the cooling water loop is refilled with the proper quality water. The unit is started. Now the condenser water regulating valve is only halfway open while maintaining a proper condenser discharge pressure.

UNIT 82—REVIEW QUESTIONS

1. What are the two common mechanical-draft cooling tower arrangements?
2. How does an induced-draft cooling tower differ from a forced-draft tower?
3. What is cooling tower fill material?
4. What is an advantage of a crossflow tower as compared to a counterflow cooling tower?
5. What is a cooling tower plume?
6. What is the working principle for an atmospheric-draft cooling tower?
7. What type of heat is required to evaporate water?
8. Where does the heat come from to evaporate water in a cooling tower?
9. Can a cooling tower cool below the outside wet-bulb temperature?
10. What is meant by cooling range?
11. What is meant by the approach?
12. How is the heat load for a cooling tower calculated?
13. What is meant by drift?
14. Theoretically, how much water evaporates in a cooling water tower?
15. What is blowdown?
16. How much makeup water is required for a cooling tower?
17. 1 psi is equal to how many feet of head?
18. Not including friction, what is the static discharge head for a water line 30 ft high?
19. How should the circulating pump be located between the condenser and the tower?
20. In addition to preventing scale, water treatment should protect the system components against what other deteriorating condition?

UNIT 83

Thermal Storage Systems

OBJECTIVES

After completing this unit, you will be able to:

1. list the different types of ice thermal storage systems.
2. describe the operation of ice thermal storage systems.
3. explain why thermal storage systems are used.
4. list the benefits of thermal storage systems.
5. explain the modes of operation for thermal storage systems.

83.1 INTRODUCTION

Thermal storage is the temporary storage or removal of heat for later use. An example of thermal storage is the storage of solar heat energy during the day to be used at a later time for heating at night. In the HVACR field, this type of application using thermal storage for heating is less common than using thermal storage for cooling. An example of the storage of “cold” heat removal for later use is ice made during the cooler night hours for use during the hot daylight hours (Figure 83-1). This ice storage is produced when electrical utility rates are lower. This is often referred to as “off-peak” cooling.

When used for the proper application with the appropriate design, off-peak cooling systems can lower energy costs. The U.S. Green Building Council, as described in Unit 68 has developed the Leadership in Energy Efficiency and Environmental Design (LEED) program to encourage the design of high-performance buildings that will help protect our environment. The increased levels of energy performance by utilizing off-peak cooling may qualify for credits toward LEED certification.

83.2 THERMAL STORAGE SYSTEMS

The advantages of thermal storage are the following:

- Commercial electrical rates are lower at night.
- It takes less energy to make ice when it is cool at night.
- A smaller, more efficient system can do the job of a much larger unit by running for more hours.

Most thermal storage applications involve a 24-hour storage cycle, although weekly and seasonal cycles are also used. In the context of the energy-efficient system applications, storage of cooling is the most popular. For HVACR purposes, water and phase-change materials (PCMs)—particularly ice—constitute the principal storage media. Water has the advantage of universal availability, low cost, and transportability through other system components. Ice, however, will absorb more heat than water and therefore has the advantage of taking up less space.

Make ice at night...

...to cool buildings during the day

Figure 83-1 Ice-storage system. (Courtesy of CALMAC Manufacturing Corporation)

A stratified water thermal storage system capable of providing 24,628 ton-hours of thermal storage is shown in Figure 83-2. Specially engineered diffusers or nozzles distribute warm water at the top of the tank and cool water at the bottom. This provides for a separation between the cool supply water and the warm return water. This 3.3-million-gallon storage tank is filled with chilled water every night.

Figure 83-2 Stratified water thermal storage tank. (Courtesy of Office of Energy Efficiency and Renewable Energy, U.S. Department of Energy)

Then every day from noon until 8 PM the chilled water is used to meet the cooling load. Thermal storage water systems can also serve to provide large volumes of water on-site for fire protection systems.

83.3 MODES OF OPERATION

There are five modes of operation of a cooling storage system that stores and releases thermal energy.

Charging Storage

In charging storage, the refrigeration system is extracting heat from the storage vessel. This would be preferably done during an off-peak period. If this is a water-storage system, then the water would be cooled. For an ice-storage system, ice would be formed.

Simultaneous Recharging Storage and Live Load Chilling

In simultaneous recharging storage and live load chilling, some of the refrigeration capacity is being used by the load at the same time the storage is being recharged. This situation occurs when there is extra capacity available. Rather than operating the refrigeration system at partial load, it is operated at full load with the additional cooling applied to the storage tank. This is preferred during off-peak periods when the cost of operation is low.

Live Load Chilling

Live load chilling is identical to normal water chiller operation, providing cooling as needed. In this situation, no cooling of the storage tank is taking place. All of the cooling capacity is directed to the building load.

Discharging and Live Load Chilling

In discharging and live load chilling, the refrigeration unit operates and the storage vessel is being discharged at the same time to satisfy the cooling load requirement. In this case, the cooling demand may be so high that additional cooling is required. Another scenario is that the peak load cost is high. The refrigeration system is operated at reduced load during this high-cost period, with the storage system making up the difference.

Discharging

In discharging, cooling needs are met only from the storage, with no refrigeration system operating. The storage tank could be used during peak loads when costs are high. This could also be used during low-demand periods when operation of the refrigeration system at low loads is undesirable. Another scenario is during a power outage when the emergency power supply is limited. The uninterrupted power supply for large computer systems will come on automatically, and these can generate a considerable amount of heat. The emergency power may not be sufficient to run the chiller unit itself, but the auxiliaries can be run and cooling supplied from the cold storage.

83.4 SELECTING THE METHOD OF OPERATION

Thermal storage, particularly ice storage, has its roots in applications involving short-duration loads, with relatively long times between loads. The classic examples are churches, sports facilities, and older movie theaters. The peak cooling load would only occur during scheduled events when the spaces are occupied. Current systems take into account these peak demand periods, but they are also now being primarily designed to offset increasing electric utility rates, day rate schedules, and large demand charges for electric power.

Thermal storage systems are typically classified as being either full storage or partial storage. The essential purpose of ice storage is to make ice while the electrical power rates are low. Full thermal storage systems will generate ice when the costs are lowest during the off-peak periods, typically at night. This ice is then melted to cool the building during the daytime hours while the large-capacity refrigeration chiller is shut down. Partial thermal storage systems differ in that they utilize a reduced-size refrigeration chiller that is operating along with the melting ice to cool the building. The optimum system type is derived from an analysis of all the elements involved, including the following:

- Total cooling load
- Total daily ton-hours of load (the sum of each of the hourly loads in a day's use)
- Available ice recharging time
- Steady loads and temporary loads
- Energy cost, peak and off-peak cost, and hours of billing
- Space for storage
- Relative costs of type of systems

Water-based thermal storage has certain specialized applications and has been successfully applied many times. However, there are inherent problems with this type of system. It is difficult to provide stratified storage temperatures, so that the recirculated, warmer water does not disturb the stored chilled water. Due to the large volume of water required, there are space and structural limitations. Open systems will require water treatment.

Using ice for storage systems has some distinct benefits. These systems can vary in size. Ice-storage systems are practical on systems as low as 5 tons. Applications utilizing ice-storage systems require modifications of conventional system designs. Ice provides cold (33°F –34°F) water for cooling and has the following advantages:

- Colder water provides a large temperature differential, which means less flow will be required for a given cooling load.
- Reduced flow rates call for smaller pipes and lower pumping costs.
- Colder water provides for lower leaving-air temperatures from cooling coils.
- Colder supply air will absorb more heat; therefore, less air needs to be delivered by the fan.
- Reduced fan airflow (CFM) calls for smaller fans and ductwork.

Figure 83-3 Thermal storage system schematic.

TECH TIP

Because of the high energy efficiency obtainable through thermal storage systems, many manufacturers are working on applying this concept to smaller residential systems. As these become more commonly available, they can provide significant energy savings to homeowners.

83.5 ICE-ON-COIL (EXTERNAL MELT) SYSTEMS

In these types of systems, multiple banks of hot-dipped galvanized steel coils are submerged underwater in field-constructed concrete tanks. Refrigerant is circulated through the inside of the coils to generate ice on the outside. The refrigerant circulated may be a direct-expansion type, but the most common kind is a system-circulating glycol supplied from a chiller (Figure 83-3). This type of system is commonly used for district cooling or for systems where cold temperatures are required.

Full thermal-storage systems have two modes of operation, referred to as “ice-build” and “melt-out.” During the ice-build phase, low-temperature glycol is circulated through the coils. For most air-conditioning applications, a solution of water and 25 to 30 percent ethylene glycol is used. The glycol warms as it passes through the coil, which forms an ice taper

that is thicker near the inlet and thinner near the outlet. This can lead to wasted volume in a thermal storage tank (Figure 83-4a). To increase efficiency, countercurrent flow circuits are utilized (Figure 83-4b). Elliptical-tube coil design also allows for better ice-packing efficiency (Figure 83-5). This is the ratio of the volume actually formed and stored in comparison to the available space for ice around the coil assembly, excluding the necessary clearance spaces.

The amount of ice formed in the storage system can be determined by measuring the water level in the tank. It will increase and rise as the ice is being formed because the ice is less dense than the water. Ice thickness controllers using conductivity measurement are also used to sense the thickness of the ice. When the ice-build is complete, the controllers shut off the glycol flow to the ice coils. In addition, an air-agitation system consisting of perforated PVC pipes located beneath the coils and supplied with low-pressure air from a blower is used during both the ice-build and ice-melt-out phases.

The melt-out phase for an external melt system begins as the 32°F tank water is circulated to the building to provide the required cooling. The warm water returning to the system will begin to melt the ice on the tubes from the outside in. During the melt, the ice surface area is reduced. With about 50 percent of the ice remaining on the tubes, the water temperature will begin to increase. Because the water temperature slowly begins to rise during the melt-out phase, this type of application is suitable for cooling loads that are high early in the cycle and slowly go down later in the cycle.

83.6 ICE-ON-COIL (INTERNAL MELT) SYSTEMS

Internal melt systems also have an ice-build phase. However, during the melt-out phase, warm glycol is circulated from the building load back to the storage tank through the inside of the heat exchanger in such a manner as to melt the ice from the inside out. Because the glycol temperature slowly begins to lower during the melt-out phase, this type of application is suitable for cooling loads that are low early in the cycle and slowly increase later in the cycle.

Figure 83-5 (a) Round-tube ice coil—reduced packing efficiency; (b) elliptical-tube ice coil—increased packing efficiency.

The storage tanks utilized for internal melt systems are manufactured in a variety of sizes, from 45 to over 500 ton-hours (Figure 83-6). They are well-insulated, seamless, one-piece tanks of polyethylene containing a spiral-wound polyethylene-tube heat exchanger (Figure 83-7). Water containing 25 percent ethylene glycol is circulated through the heat exchanger at approximately 25°F during the ice-build phase. About 95 percent of the water in the tank is frozen solid. Since the ice is built uniformly throughout the tank, the water does not become surrounded by the ice during the freezing process, allowing it to freely move and prevent damage to the tank.

This type of system can be configured for either full- or partial-storage conditions. The charge cycle for a partial-storage system is shown in Figure 83-8. During the off-peak utility hours, the glycol leaving the chiller is set for a temperature of 25°F. In this cycle, the glycol is used only for building ice and is diverted back through the chiller until approximately 95 percent of the water inside the tank has been frozen solid.

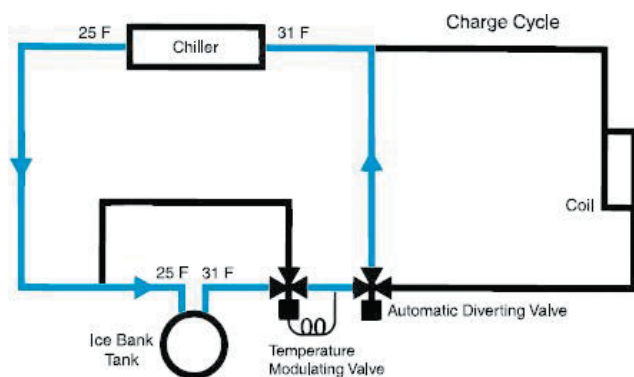

Figure 83-8 Partial thermal energy-storage charge cycle. (Courtesy of CALMAC Manufacturing Corporation)

Figure 83-9 Partial thermal energy-storage discharge cycle. (Courtesy of CALMAC Manufacturing Corporation)

The partial-storage discharge cycle is shown in Figure 83-9. During the heat of the day, the glycol temperature leaving the chiller is set to a temperature of 52°F. Because the chiller will be used in combination with the ice-storage tank, it can be sized 40 to 50 percent smaller than comparable HVAC non-storage-type systems. The temperature-modulating valve will allow a portion of the glycol to flow through the storage tank for the ice-melt phase to further cool the glycol. This lower-temperature glycol is then mixed with glycol bypassing the tank to control the final glycol outlet temperature at 44°F. The glycol at 44°F is directed to the air-distribution system cooling coil to remove the heat from the air being circulated within the building.

The full-storage system ice-build phase occurs during the off-peak utility hours with the refrigeration chiller in operation. During the heat of the day, the refrigeration chiller is shut down. However, the glycol continues to circulate through the storage tank during the ice-melt-out phase to supply cooling for the building. Similar to the operation of the partial-storage cycle, the modulating valve is used to mix a portion of the warmer glycol returning directly from the coil with the colder glycol passing through the storage tank to maintain the set temperature of the glycol supplied to the coil.

There may also be periods when the storage tank is bypassed altogether, referred to as live-load chilling. This may occur when electrical rates are low and the ice-storage tank is being conserved for later use or for mild-temperature days in the spring and fall when cooling demand is relatively low. For live-load chilling, the thermal energy storage tank will be bypassed completely, and the refrigeration chiller will be used to meet the cooling demand, as shown in Figure 83-10.

Figure 83-10 Bypass cycle (chiller-only cooling).

Figure 83-11 Spherical container for ice thermal storage.

The polyethylene construction and seamless tank design result in a low-maintenance demand for this type of system. The water level of the storage tank is checked annually. A biocide is added to the water every 2 years. The concentration of the glycol solution is checked annually.

83.7 ENCAPSULATED ICE-STORAGE SYSTEMS

In this type of system, a number of water-filled containers are placed inside a tank. A glycol solution fills the tank and circulates over and around the containers. Some containers are spherical, with dimples to allow for expansion on freezing, as shown in the diagram in Figure 83-11. Other containers are flat and rectangular like a giant hot-water bottle or annular, shaped like a donut. These containers are stacked in storage tanks that can vary in shape and design. In this type of system, the ice is formed within each spherical container from contact with a cold glycol solution, as shown in Figure 83-12.

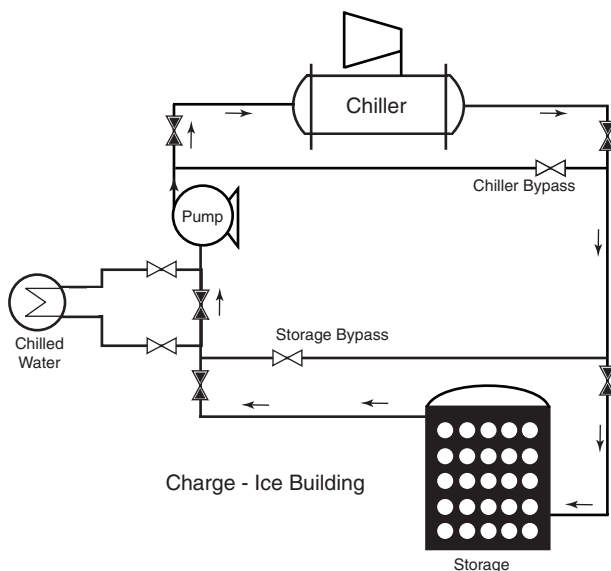

Figure 83-12 Encapsulated ice-storage system—ice building.

The piping in and out of the tank must create a flow path that is effective for both charging and discharging. The control system monitors the liquid level of the tanks to determine the amount of ice formed. As ice is formed, the containers expand, which raises the glycol level in the tank. The tank level is monitored to determine when the system is fully charged.

The economic factors for this type of system include storage tank shape, configuration, and installation. The non-managed flow path of encapsulated ice-storage systems does not offer repeatable performance. Because of this, there is a tendency for designers to oversize them. Also because of the design, encapsulated ice-storage systems typically will use more glycol as compared to ice-on-coil systems.

83.8 ICE-HARVESTING SYSTEMS

Ice-harvesting systems are another application of industrial ice makers/water chillers. These types of systems require large and heavy equipment with limited configurations and so are becoming less common. These units build ice in sheets on the surface of vertical refrigerated plates. The ice is harvested by slightly warming the plates with refrigerant discharge gas, which causes the ice sheets to break away from the plates and fall into a water-filled storage tank. The sheets of ice break up when they hit the water, providing many exposed ice surfaces for heat transfer to the water. The thin sheets of ice provide a very even discharge cycle, with consistently low water temperatures. Monitoring of the tank level determines refrigeration operation.

The storage tank must be constructed with weirs (a weir is like a dam) to prevent the ice from getting into the circulation system. Since the ice floats and distributes itself in the tank, water flow distribution is less critical than with some of the other systems.

SERVICE TIP

Ice-harvesting equipment is the most complex of the various thermal storage systems. However, it is often the most efficient method of ice production when properly set up. A major factor in the efficiency of ice harvesters is the actual harvesting cycle. Harvesting is typically performed by diverting the hot condenser gas back into the evaporator plate where the ice has formed. This momentary heating causes the ice to release, clearing the evaporator surface for more ice to form. Manufacturer guidelines list recommended harvest times to optimize ice production.

83.9 THERMAL STORAGE FOR HEATING

Applications of thermal storage for heating in the HVAC field are less common than cooling. However, there are applications that have been becoming increasingly popular. These systems usually require some type of a thermal storage tank or reservoir.

Heat Pump Applications

Most ground- and water-source heat pumps take advantage of sources of heat without necessarily requiring a thermal storage tank. However, heat pumps can be used in combination with thermal storage systems. As an example, rooftop solar collector panels can be used during the day to heat water that is stored in a thermal storage tank. During the cooler evening hours, the heat pump can be used to remove heat from the storage tank and deliver it to the building.

Thermal Storage Under-Floor Heating

Some homes are designed with electric cables or heating panels buried 4–12 inches deep in a bed of sand. The cement slab for the building is then poured on top. During the low-cost, off-peak hours, the sand is heated to create a thermal reservoir beneath the floor. During the cooler evening hours, the heat from the floor will be continually radiated into the building.

Coil-type mats are used for permanent and/or temporary ice applications, such as skating rinks (Figure 83-13). Similar mats are also used for subfloor heating and other applications, such as turf warming for year-round plant growing at stadiums and greenhouses, snow melting for athletic fields and dog tracks, and permafrost prevention for refrigerated warehouses and ice-skating rinks. A heated liquid is circulated through a series of polyethylene tubes. Lake-coupled geothermal heating systems involve laying a series of plastic tubes near the bottom of a lake to be used in combination with a heat pump system. Standard-size preassembled mats are commonly available, as are custom designs to meet almost any application.

Boreholes

For this application, an array of bored holes resembling standard drilled wells is spaced in a grid. A plastic pipe with a U bend is then inserted into each borehole. Solar heaters and a pumping system provide for a flow of hot water down into the boreholes to heat the ground during the summer

months. This heat is then recovered and sent to the building during the winter months.

UNIT 83—SUMMARY

Most thermal storage systems encountered in HVACR are used for cooling. The storage of chilled water is popular, but this requires a large storage tank that is typically of the stratified design. Ice-storage systems require less space and are the most popular type. There are a number of different types of ice-storage systems, such as ice-on-coil internal melt, ice-on-coil external melt, ice harvesting, and encapsulated ice-storage systems. Thermal storage systems allow for charging during periods of low-cost electrical off-peak rates. This stored cooling capacity is then discharged during high-cost peak periods, which reduces or even eliminates the need to run the chiller units. Thermal storage systems therefore will reduce total operating costs.

WORK ORDERS

Service Ticket 8301

Customer Complaint: Ice Too Thin

Equipment Type: Ice-on-Coil System

The ice builder is charging very quickly and the ice formation is not very thick. During discharge periods, the total cooling period is short. The technician first checks the refrigeration chiller, and it was found to be operating normally. The ice formation is uniform across the coil, which indicates good refrigerant flow and water coverage. However, the layer of ice is thin. The technician locates the ice sensors used to monitor the ice thickness and replaces them. Now the unit charges to the proper ice thickness and the discharge period is considerably longer.

Service Ticket 8302

Customer Complaint: Insufficient Ice Buildup

Equipment Type: Ice-on-Coil System

The glycol coil is not freezing the ice solid, and the refrigeration unit is running for prolonged periods during the charging cycle. The technician first checks the refrigeration chiller and determines that the load on the unit is low, although the charging cycle is in progress. The glycol temperature difference into and out of the chiller is also low, indicating little heat transfer. The technician checks the glycol circulating pump and discovers a low suction pressure and a low discharge pressure. There is a restriction to flow somewhere in the glycol system. The technician is told that a glycol leak was repaired a few days back. Because there is no glycol available, only water is added back into the system to replace the glycol that leaked out. Evidently, ice has been forming inside the glycol circuit and restricting flow.

Figure 83-13 IceMat® being unrolled for installation. (Courtesy of CALMAC Manufacturing Corporation)

The technician recommends that the system be shut down to allow for the ice inside the circuit to melt. A glycol sample will be taken and tested for specific gravity. This will determine how much of the existing glycol solution needs to be drained and replaced with new glycol. When this is completed, the system should operate normally.

Service Ticket 8303

Customer Complaint: Ice Harvest Not Uniform

Equipment Type: Ice-Harvesting System

The ice-harvesting machine when working properly provides for uniform sheets of ice that drop from the coil into the water-filled storage tank. But now the ice is becoming too thick. To get the ice to drop off, the unit needs to be shut down until the sheet melts and falls. The technician checks the hot-gas solenoid valve. This valve is set on a timer to automatically direct hot gas from the compressor through the evaporator coil so that the ice melts and falls. The gas solenoid valve electromagnet solenoid coil is tested for electrical resistance and is found to have infinite resistance, which indicates that it needs to be replaced. The replacement is a fairly simple process of wiring in a new solenoid. The ice harvester is now working properly.

UNIT 83—REVIEW QUESTIONS

1. What are the advantages of thermal storage systems?
2. What common types of phase-change materials are used for thermal storage systems?
3. What is an advantage of ice-storage systems as compared to water-storage systems?
4. What is meant by a stratified thermal water-storage tank?
5. What is meant by charging storage?
6. What is meant by discharging storage?
7. Would a system ever be charged and discharged at the same time?
8. What is meant by live-load chilling?
9. What are the determining factors for when to charge and when discharge from thermal storage?
10. What is the difference between full and partial thermal storage systems?
11. What can happen if the ice sensor for an ice-on-coil system is faulty?
12. What type of regular maintenance is required for an ice-on-coil internal melt thermal energy system?
13. What percentage of ethylene glycol is commonly used for an ice-on-coil (external melt) system?
14. Why is clear ice formation on an ice-on-coil thermal storage system desired?
15. Why do spherical encapsulated ice containers have dimples on their exterior surface?
16. How does an encapsulated ice energy-storage system compare to an ice-on-coil energy storage system?
17. How is the ice harvested from the evaporator plates in an ice-harvesting system?
18. Of all the thermal storage systems for ice, which is the most complex?
19. What are the advantages of water for use in a thermal energy-storage system?
20. What melts the ice on an ice-on-coil external melt thermal energy storage system?

UNIT 84

Food Preservation

OBJECTIVES

After completing this unit, you will be able to:

1. explain how various refrigeration processes are used to preserve perishable food.
2. explain the purpose and methods of flash freezing.

3. list the design consideration for a long-term storage building.
4. compare short- and long-term storage of food products.

84.1 INTRODUCTION

The perishable food industry is one of the largest industries in the country. An industry of this size is extremely important, and proper refrigeration is an important factor in the success of this business.

Perishable foods can be classified as follows:

- Meats
- Poultry
- Seafood
- Fruits
- Vegetables
- Dairy products

Figure 84-1 Blueberries are a fruit, picked when ripe, and can be preserved temporarily with refrigeration; but for long-term storage, they are flash frozen.

84.2 PRESERVATION OF PERISHABLE FOODS

Perishable foods can be divided into three groups: animal, vegetable, and dairy products. Each group requires separate treatment to preserve the products and to keep them palatable. The storage of animal products requires the prevention of deterioration of the nonliving products. Fruits and vegetables, however, are as much alive while they are being transported as they were while growing and require an entirely different set of preservation conditions (Figure 84-1). The principal causes of food spoilage are as follows:

- **Microbiological** These include bacteria, molds, and fungi.
- **Enzymes** These are chemical in nature and do not deteriorate.
- **Oxidation changes** These are caused by atmospheric oxygen coming in contact with the food, producing discoloration and rancidity.
- **Surface dehydration** In freezing, this is called freezer burn.
- **Wilting** This applies to vegetables that lose their crispness.
- **Suffocation** Certain fresh vegetables must have air. When sealed in cellophane bags, the bags must have holes.

SERVICE TIP

It is very important that the equipment used to process, store, or serve food products be cleaned. Foodborne contaminants are a major health issue, and only stringent cleaning of equipment can control this problem.

84.3 MEATS, POULTRY, AND SEAFOOD

Although poultry is a meat, it is generally classified in a separate category by the United States Department of Agriculture (USDA). In regard to preservation, all of these products deteriorate through the action of bacteria. Sanitation is the most important factor in controlling bacteria. Air has many forms of bacteria present. One of the best ways of controlling bacterial infection is through the use of germicidal or ultraviolet lamps.

Meats

Common types of meat include beef, pork, and lamb. The method of handling, preservation, and storage will depend on the type of meat product. As an example, a side of beef is aged, a whole pork ham and bacon are normally smoked

and sausage is cured in a dry room. The aging process for beef allows its natural enzymes to act as a tenderizer. This utilizes the good effects of the enzymes without the harmful effects of bacteria. Oxidation is detrimental to meats, causing undesirable appearance and deterioration of the flavor. Dehydration can be controlled to a large extent by maintaining high humidity in the storage room. High humidity also protects against moisture loss, which lowers the weight of the meat.

Pork should be rapidly cooled after it is cut. This prevents destructive enzymatic action that causes discoloration, rancidity, and poor flavor. The keeping qualities of a variety of dry sausages produced depend on curing ingredients, spices, and removal of moisture from the product by drying. Dry rooms are used to remove about 30 percent of the moisture, to a point where the sausage will keep for a long time virtually without refrigeration. This process is used as an alternative to the smoking process. The U.S. Department of Agriculture (USDA) requires that a dry room for sausage be maintained at temperatures above 45°F, and the length of time in the room depends on the diameter of the sausage after stuffing and method of preparation.

Poultry

Problems associated with the preservation of poultry are similar to those of meat in many respects, except that poultry spoils much faster. Poultry, however, can be precooled by the use of cold water without detrimental effects. This is a relatively simple and effective process and therefore quite generally used. Bacteria and enzyme action is useful only in preserving game birds, as such action has a tendency to enhance the “game flavor.”

CAUTION

All meat products have some level of bacteria. However, poultry has a particularly high level of *Salmonella*. If you cut yourself while working on equipment that processes or stores any raw meat, especially poultry, you must take particular precautions to ensure that the cut does not become infected. If it does become infected, you should seek medical advice.

Seafood

This product is the most perishable of all the animal foods, yet there is a vast difference in the keeping quality of different kinds of fish. For example, swordfish can be kept refrigerated for 24 days and be in a more palatable condition than mackerel refrigerated for 24 hours. Commercial fish are usually refrigerated with ice.

84.4 FRUITS AND VEGETABLES

The unique situation with fruits and vegetables is that they are still alive after they are picked. They grow, breathe, and ripen. Most fruits and vegetables are picked in an unripe

condition. The best tasting products are ripened before they are picked. The purpose of refrigeration is to slow down the ripening process so that these products can reach consumers before spoiling.

Vegetables quickly lose their vitamin content when surface drying takes place. It is interesting to note that products shipped from California to Chicago that have been properly iced after harvest will be fresher than produce supplied from Illinois farms and shipped to a Chicago market without being iced.

SERVICE TIP

All fruits and vegetables give off some quantity of moisture. This moisture release is called respiration. The ability to cool a product can be significantly affected by its rate of respiration due to the added latent load it represents.

Another way to improve the product when it reaches the user is to package it. This cuts down on surface drying. Packages are usually made of cellophane or some similar plastic product. These containers must have holes so that the product can breathe (exchange oxygen and CO₂). Otherwise, the product will die, and a dead product will spoil rapidly.

A number of products require special treatment—bananas, for example. These are picked green and must be ripened for marketing. Banana ripening is initiated by the introduction of ethylene gas. For this to be effective, banana rooms must be airtight. Refrigeration is provided by using a refrigerant other than ammonia, because leaks will damage the fruit. Banana rooms are cooled using 45°F–65°F air. Keeping a design temperature difference of 15°F and a refrigerant temperature of 40°F is considered good practice.

Freezing Vegetables

All prepared vegetables are precooked and cooled before freezing, as discussed in the previous section. Refrigeration is used for every step in the preservation process. This includes the raw product cooling and storage facility, cooling the product after blanching, freezing the product, and finally storing the product in a warehouse. Loads vary widely depending on the product.

In vegetable facilities that operate only for short periods at peak capacity—1,500–2,500 hr/yr—spare equipment cannot be economically justified, and good maintenance is important to avoid downtime losses.

Freezing Potatoes

Prepared potato products in various forms dominate the frozen ready-to-use vegetable group and are processed year round. Products include french fries, hash browns, twice-baked potatoes, potato skins, and boiled potatoes. French fries are probably the most popular.

Raw potatoes for fries are steam peeled and trimmed and then cut into desired shapes. The slivers are graded out

for use as puffs, tots, and wedges. The fries are blanched and then partially dried and oil fried. They are frozen on a straight-belt freezer system with three separate conveyors for precooling and totally freezing the fries to 5°F–10°F. Sorting is done at 15°F and packaged in an air-conditioned area.

84.5 DAIRY PRODUCTS

Sanitation is extremely important in all stages of handling milk. The bacteria content of milk must be controlled. Mechanical refrigeration begins to cool it even during milking, from 90°F down to 50°F within the first hour and from 50°F down to 40°F within the next hour. As more milk is added, the blended liquid must not rise above 45°F. Limits are set for the number of bacteria (the bacteria count) for milk supplied by the producer.

Milk is stored in insulated or refrigerated silo-type tanks that maintain a 40°F temperature. After milk is pasteurized and homogenized, it is again cooled in a heat exchanger (a plate or tubular unit) to 40°F or lower and packaged.

Butter

Butter is manufactured from 30 to 40 percent cream obtained from the separation of warm, acidified milk. It is cooled to 46°F–55°F and then churned to remove excess water. Butter keeps better if stored in bulk. If kept for several months, the temperature should not be above 0°F and preferably below –20°F. For short periods, 32°F–40°F is satisfactory. If stored improperly, the quality of butter deteriorates from absorption of atmospheric odors, loss of weight through evaporation, surface oxidation, growth of microorganisms and resulting activity of enzymes, and low pH (high acid) of salted butter. Low temperatures; a clean environment; use of a good quality cream; avoidance of light, copper, and iron; and adjustment of the pH to 6.8 to 7.0 eliminates most of these problems.

Cheeses

Cheeses are refrigerated to prevent too rapid mold growth. The surface must be kept moist or the cheese will become hard and brittle. Moisture, meanwhile, facilitates mold. While some mold enhances the flavor, too much mold creates waste because it must be removed before sale. The ideal storage temperature for various types of cheese is in the range of 30°F to 34°F for natural cheeses and 45°F for processed cheeses. Maximum temperatures range from 45°F to 60°F for the natural cheeses, while the processed cheeses may be kept on open shelves at 75°F.

TECH TIP

Many cheeses contain active organisms that provide the cheese with its unique flavor. Improper storage of these cheeses can damage these organisms and the flavors that they provide the cheese. It is very important that the specific temperature and humidity range for a particular cheese be obtained from the customer before a storage system is established. Some cheeses have very broad temperature and humidity tolerances, while others are extremely narrow and sensitive. The active organisms in cheese can also continue to generate heat after the cheese is in the cooler. This contributes additional load and extends the time required to cool the product (pull-down time) to its final storage temperature.

Eggs

Eggs should be refrigerated at all stages of handling and storage. Shell eggs account for about 75 percent of all eggs used. Table 84-1 lists the temperatures, humidity, and time they can be stored.

Research has shown that microbial growth associated with *Salmonella* can be controlled by holding eggs at less than 40°F. This has led to major changes in storage and display areas not refrigerated or inefficiently refrigerated. All egg storage areas should maintain ambient temperatures of 45°F; however, with mechanized processing and packaging procedures that insulate the eggs within cartons, it may require up to 1 week of storage before the eggs reach the temperature of the storage room. If shipped earlier to sell a “fresh” product, eggs are only partially cooled. Methods are being developed to improve cooling in the processing plant.

Shipment in refrigerated trucks is mandatory. Problems that arise are associated with the truck design, manner of loading, size of the shipment, and distance.

84.6 FROZEN FOODS

The freezing of food, although highly product specific, is basically a time/temperature-related process of three phases: (1) cooling to freezing point, (2) changing the water in the product to ice, and (3) lowering the freezing temperature to optimum frozen storage temperature. Product differences as well as quality relate to the specific values and to the rates of these stages.

Table 84-1 Storage Period of Eggs at Various Temperatures and Humidity Conditions

Temperature (°F)	Relative Humidity (%)	Storage Period
51–60	75–80	2–3 weeks
45	75–80	2–4 weeks
29–31	85–92	5–6 months

The following factors are considered in selecting a freezing system for a specific product:

- Special handling requirements
- Capacity
- Freezing times
- Quality consideration
- Yield
- Appearance
- First cost
- Operating costs
- Automation
- Space availability
- Upstream/downstream processes

84.7 FLASH FREEZING

Quick freezing was first undertaken by Clarence Birdseye in 1924. This essential process produces small ice crystals that are less damaging to the product. Ideally, the ripe produce should be frozen immediately after harvest—the sooner the better. Small packages are better to freeze than large packages because the interior freezes more quickly.

Flash freezing is the term most commonly used today. Flash freezing generally denotes quick freezing at cryogenic temperatures (below -238°F). Many quick freezing applications such as blast freezers operate at low temperatures but still well above cryogenic. Even so, the term flash freezing is generally preferred to describe most quick freezing processes.

Small packages may be frozen on or between refrigerated plates or in a “blast” freezer. Foods are frozen at temperatures between -20°F and -5°F . Freezer burn should be avoided. This is the condition of surface oxidation that causes discoloration of the product. It is prevented by packaging in airtight containers or by waxing or glazing the product. Ice glazing is used to prevent surface drying of fish. Fruits are often glazed with a sugar syrup to prevent oxidation.

TECH TIP

As the water in products begins to freeze, it forms very long, sharp crystals. The slower the freezing process, the larger these crystals become. If the crystal size is large enough, it will puncture the cell walls of the product being frozen. When the product thaws and the ice crystals melt, fluids in the individual cells of the product can be lost. This loss of fluid results in a significant decrease in the quality of the product. To reduce this problem, many products are flash frozen. This process produces the smallest possible crystal form, thus reducing the loss of special product fluids and maintaining product quality.

Vegetables must be blanched before freezing. This consists of placing the product in boiling water or steam to kill bacteria and to stop enzyme action. Air is removed from citrus juice before freezing.

Commercial freezing systems can be divided into four groups:

- Air-blast freezers
- Contact freezers
- Immersion freezers
- Cryogenic freezers

Air-Blast Freezers

Air-blast freezing can best be described as a convection system, where cold air at high velocities is circulated over the product. The air removes heat from the product and releases it to an air refrigerant heat exchanger before circulation occurs again.

The air-blast freezer using a stationary tunnel produces satisfactory results for practically all products, in or out of packages. Products are placed in trays that are held in racks, placed so that air bypass is minimized. Air-blast freezers can also be mechanized to provide a continuous process. Conveyor-belt-type freezers use vertical airflow and greatly improve the contact between air and product.

An example of a single-conveyor-belt blast freezer for a blueberry-processing plant is shown in Figure 84-2. The blast freezer is fed a continuous supply of blueberries, as shown in Figure 84-3. The blueberries are first cleaned to remove twigs and stones in a float tank (Figure 84-4). After cleaning, the belt delivers the blueberries to the blast freezer (Figure 84-5).

This method is commonly used for freezing blueberries. Once frozen, blueberries should not stick together in clumps but be separate from one another. A frozen container of blueberries should rattle when shaken. The blueberries will enter the tunnel shortly after harvesting, so they will be laden with moisture. If frozen in a container, the blueberries will all stick together. On the conveyor, they are spread out to allow the low-temperature air to circulate up through them as they pass through the tunnel. After flash freezing, the blueberries are placed in large walk-in coolers for storage.

A slightly different method uses air to move the product rather than a belt. Solid particulate products such as

Figure 84-2 Inside one of the air-blast freezers at a blueberry-processing plant.

Figure 84-3 This blast freezer is a tunnel type that flash freezes the blueberries as they pass through the unit from one end to the other.

Figure 84-4 Twigs and stones are removed from the blueberries prior to freezing.

Figure 84-5 A series of conveyor belts continuously deliver blueberries to the blast freezer.

peas, sliced and diced carrots, and shredded potatoes or cheese are floated upward and through the freezer by streams of air. The product is frozen in 3–11 minutes by refrigerant temperatures of -40°F . These freezers are packaged, factory-assembled units.

Contact Freezers

Contact freezers are conduction-type freezers. Products are placed on or between horizontal or vertical refrigerated

plates that provide efficient heat transfer and short freezing time. They can be arranged as racks with the product placed directly on top of the refrigerated plate. This method is sometimes used for seafood such as fillets of fish. Product that is 2 to 3 in thick such as this is used with contact freezer applications.

Immersion Freezers

Immersion freezing is the fastest method available for flash freezing. The product is passed through a shallow liquid nitrogen bath, which forms an instant crust, which in turn freeze-locks in the natural flavors and moisture of the product.

Some products, such as shrimp, are frozen by immersion in a boiling, highly purified refrigerant. The surface of a sticky or delicate product is “set” by this rapid freezing, reducing dehydration and improving the handling characteristics of the product. The product is then removed and the freezing process is completed in a mechanical freezer. In these systems, the refrigerant is recovered by condensing on the surface of refrigerated coils.

Cryogenic Freezers

Cryogenic freezers utilize both convection and/or conduction by exposing food to temperatures below -76°F in the presence of liquid nitrogen or liquid carbon dioxide refrigerants. Liquid nitrogen boils at -320°F , and carbon dioxide boils at approximately -110°F . The freezers may be cabinets, straight-belt freezers, spiral conveyors, or liquid immersion freezers. The boiling liquid comes in direct contact with the product. After use, the refrigerant is wasted to the atmosphere. Spiral freezers can be used for flash freezing on trays. Internal freezer temperatures can reach -150°F . While operating costs are high, the small initial investment makes this economical for certain foods, such as delicate and difficult to freeze products such as bakery products and entrees.

84.8 REFREEZING

When a vegetable product is in a frozen state, for all practical purposes it is considered “dead”; however, microbes and enzymes may remain there in an inactive state. When thawed, a large amount of water is present from the ruptured tissues to provide a favorable environment for the growth of microbes and deterioration due to the enzymes. All of these processes serve to lower the quality of the product and could continue after refreezing. The product should be heated sufficiently to kill these destructive agents before refreezing. Some canneries freeze products to prevent spoilage until they can schedule the final canning process.

84.9 FOOD PROCESSING

The production of precooked and prepared foods developed into an important industry during the last half of the twentieth century. These foods, which include ready-to-use foods

for main dishes and meals, vegetables, and potato production, require refrigeration and air-conditioning facilities.

Main dishes, which constitute the largest group of products in this area, include complete dinners, lunches and breakfasts, soups/chowders, low-calorie/diet specialties, and ethnic meals. They are characterized by having a large number of ingredients, several unit operations, an assembly-type packaging line, and final refrigerating or freezing of individual packages or cartons. Production falls into the following operations in the processing plant:

1. Preparation, processing, and unit operations. This involves the initial preparation of all ingredients to be assembled, including refrigeration and/or freezing needs. These require specific attention to individual requirements for selecting processes, equipment, space, controls, and safeguards.
2. Assembly, filling, and packaging. This includes all handling of components for putting into containers or packages, packaging, and placing the containers and packages in refrigerators or freezers. It is considered good practice to air-condition filling and packaging bins to control bacteria and increase worker productivity.
3. Cooling, freezing, and casing. There is a constant effort to improve the economy and efficiency of production, often altering original design conditions. Space and equipment capacity allowances should be 25–50 percent for increasing requirements. Maintenance should include checking temperatures and other specific conditions of the particular product involved. Defrosting on conveyor systems should be checked when there are hang-ups or stoppages. When the position or place of packages is changed in the storage processes, the quality of the product should be closely monitored.
4. Finishing: storage and shipping. Infiltration and product pulldown loads occur when there is negative air pressure due to exhausting more air than is supplied by ventilation. This causes a serious load on the refrigeration, making it difficult to maintain proper storage temperatures.

SERVICE TIP

Many plants have requirements for hairnets and protective clothing while working around food-processing equipment. You are required to wear the same type and level of personal hygienic materials as other workers. These items may include hairnets, beard nets, lab coats, and shoe covers. It is also important that you keep your tools very clean and disinfected.

84.10 REFRIGERATION EQUIPMENT AND LOADS

Records need to be kept of operating conditions to identify poor performance and to provide guidance for new systems. These records should show conditions for time of

(a)

(b)

Figure 84-6 (a) Equipment room with two screw-type ammonia compressors; (b) ammonia screw-type compressor suction line.

day, season, on/off shift production, evaporator temperature, and equipment type/function.

The refrigerant used for many large refrigeration systems is ammonia. To avoid the hazard of a potential ammonia spill to workers in the plant, glycol chillers are used by some plants to circulate propylene glycol to evaporators located in the production areas.

Reciprocating compressors are common, but for large loads, screw-type compressors will provide for greater capacity (Figure 84-6). Unlike many other common refrigerants, ammonia is lighter than air. Therefore, ammonia condensers will not have air purge lines on the top of the condenser. An air-cooled ammonia condenser and receiver are shown in Figure 84-7.

Figure 84-7 Ammonia air-cooled condenser and receiver.

Due to its toxicity, precaution must always be taken with ammonia systems. Ammonia-detection systems are available that will continuously monitor ammonia levels for an enclosed space or equipment room (Figure 84-8).

84.11 LONG-TERM STORAGE

Freezing and thawing temperatures of animal, vegetable, dairy, and egg products vary widely. Temperatures must be maintained that preserve the quality and safety of products over the time periods required. As a result of ongoing research, lower temperatures are being recommended.

Most modern refrigerated warehouses are one-story structures. The building is designed for easy loading and unloading of tractor trailer trucks (Figure 84-9), and the inside design allows enough room to maneuver a forklift (Figure 84-10). Steel racks allow for the product to be stacked and yet still have enough air circulation to maintain the proper temperature (Figure 84-11). Even ice-making facilities will require warehouse storage (Figure 84-12). An ice and water slurry will be compressed into block ice and then bagged and stored (Figure 84-13).

Older storage buildings will have the evaporator coil located directly in the space (Figure 84-14). Today, it is usually more convenient to use penthouse refrigeration equipment rooms, as shown in (Figure 84-15). In this way, the air can be blown down into the space from the penthouse (Figure 84-16). The penthouse will contain all of the refrigeration equipment and an air handler.

Building Design Considerations

Building design consideration for long-term storage must be given to the following elements:

- Entering temperatures
- Duration of storage
- Required product temperature for maximum/minimum protection
- Uniformity of temperatures

(a)

(b)

(c)

Figure 84-8 (a) Ammonia sensor; (b) ammonia and oxygen levels for the space; (c) alarm light.

- Air movement and ventilation
- Humidity
- Traffic into and out of storage space
- Sanitation
- Light

(a)

(b)

Figure 84-14 (a) Older buildings may have the evaporator coil located in the storage space; (b) evaporator in the defrost mode with its panel closed.

Those making plans for freezer storage at vegetable-processing plants must also consider the following potential additional loads:

- Extra reserve capacity needed for product pulldown during peak processing
- Negative pressure that can increase infiltration by direct flow-through
- The process machinery load (particularly pneumatic conveyors) associated with repack operations

Figure 84-15 Penthouse located on top of the storage building.

Figure 84-16 Cold air is blown into the storage space by ducts connected to the penthouse, which is located above the building.

Regulations and guidelines for the refrigerated storage of foods have been established by the following agencies and should be familiar to the serviceperson working in these areas:

- The Association of Food and Drug Officials (AFDO)
- Occupational Safety and Health Act (OSHA)
- U.S. Department of Agriculture (USDA)
- U.S. Environmental Protection Agency (EPA)

UNIT 84—SUMMARY

In 2006, the United States consumed more heat-and-eat and thaw-and-eat food than ever in history. This trend was brought about by the advancement in food preservation, which has allowed these products to retain their appearance, flavor, and nutritional value. Without the skills and expertise of HVACR technicians, these advances would not have been possible. As more and better processes are developed, it is hoped one day that hunger worldwide could be eliminated. It is an exciting time and hopefully a profitable time to be involved in refrigeration service work.

WORK ORDERS

Service Ticket 8401

Customer Complaint: Milk Is Going Sour Too Quickly

Equipment Type: Walk-in Cooler

The technician arrives at the facility and finds that the temperature in the cooler is properly set, and the system temperature log indicates that the box is maintaining the temperature.

Upon investigation of the cooler, the technician finds that cases of eggs have been stacked too high and are blocking the airflow from the coil. This is allowing the milk, which is stored in the front of the cooler, to become too warm.

The technician shows the owner the problem, and the cases are moved. The box temperature shows an initial rise of a few degrees but quickly responds. The rise in box temperature was a result of the door being open and the full load of the box being seen by the coil. With the cases of eggs in front of the coil, the unit was really only cooling the small space behind the cases.

UNIT 84—REVIEW QUESTIONS

1. List the six categories of perishable foods.
2. What are the principal causes of spoilage in foods?
3. What is the most important factor in controlling bacteria?
4. What problems are associated with the preservation of poultry?
5. What is the most perishable of all the animal foods?
6. What is the purpose of refrigerating fruits and vegetables?
7. Describe the special treatment required for bananas.
8. Describe the special treatment required for milk.
9. What happens if butter is stored improperly?
10. What is the ideal temperature for storing cheese?
11. Using Table 84-1, determine the conditions needed to properly store eggs for 2 to 4 weeks.
12. What factors must be considered when selecting a freezing system for a specific product?
13. How can freezer burn be avoided?
14. What is the blanching process, and why should it be used before freezing vegetables?
15. Describe the process of air-blast freezing.
16. How are products frozen in conduction-type freezers?
17. Describe the cryogenic freezing process.
18. Describe the immersion process of freezing.
19. What should be done before refreezing a vegetable product?
20. What four operations are performed in a processing plant for precooked and prepared foods?
21. What operating conditions should be recorded for refrigeration loads?
22. What are some factors that must be considered when designing a refrigerated warehouse?
23. What organizations establish regulations and guidelines for the refrigerated storage of foods?

UNIT 85

Commercial Refrigeration Systems

OBJECTIVES

After completing this unit, you will be able to:

1. describe the differences between high-temperature, medium-temperature, and low-temperature refrigeration systems.

2. explain how a multiple-compressor system operates.

3. explain the operation of a defrost system for a walk-in freezer.

4. explain how to size a walk-in cooler or freezer.

85.1 INTRODUCTION

Commercial refrigeration systems serve a wide variety of purposes. The most common systems are those used for food-storage applications, such as a walk-in cooler at a grocery store or a food display case, and that is what is covered in this unit. However, with the exception of air conditioning, refrigeration is used for almost everything else that needs to be cooled. There are large commercial and industrial refrigeration systems that are designed for specialty applications such as making ice, quick freezing and storing blueberries, potatoes, fish, and pizza (see Unit 84). Refrigeration is also used in manufacturing, where it is referred to as process cooling.

There are many types of refrigeration systems, and each type is suitable for specific applications. The equipment design must ensure that the quality of the product being cooled remains satisfactory. In addition, a minimum amount of energy must be used to perform the operation. Finally, the process must be operated to comply with the laws relating to protecting the environment.

85.2 SYSTEMS

Refrigeration is divided into four broad areas based on the evaporator coil temperature. High-temperature refrigeration coil temperatures range from +20°F to +55°F. Medium-temperature refrigeration coil temperatures range from -10°F to +30°F. Low-temperature refrigeration coils range from -40°F to +10°F. Cryogenics involves a very-low-temperature process with temperatures of -250°F and below.

High-temperature refrigeration is used for product storage above freezing. When we think of high-temperature refrigeration, we usually think of food storage. Food items like milk, cheese, and fresh fruit and vegetables are stored at temperatures below 40°F and above 32°F. Storage temperatures within this range are also used for things like flowers or medicine.

Medium-temperature refrigeration is used for storing frozen foods. The most common example of medium-temperature refrigeration is a home refrigerator's freezer compartment.

Low-temperature refrigeration is used to quickly freeze and store foods. Temperatures below 0°F freeze foods

quickly to preserve their quality. Foods at these temperatures can be stored for long periods of time as compared to foods stored in the medium-temperature range. The most common example of low-temperature refrigeration is a deep freeze.

Cryogenic temperatures are used for the preservation of materials for an extremely long period of time. Materials stored at these temperatures are almost suspended in time. Maintaining cryogenic temperatures requires a lot of refrigeration and is very expensive, so this type of storage is mainly used to store medical and scientific materials.

TECH TIP

Generally, the colder a food product is stored, the longer its shelf life. For example, milk stored at 40°F in a refrigerator may only last a few days before souring, as compared to milk stored at 32°F, which may last two or more weeks before souring. Even foods that are frozen will remain at a higher quality longer the lower the storage temperature. Food in a refrigerator/freezer can be stored and used longer when the temperature in the freezer is closest to 0°F. A deep-freeze temperature is below 0°F, and foods at these temperatures can be stored for much longer periods of time while maintaining their quality.

85.3 REFRIGERATION SYSTEM COMPONENTS

The essential components required for a basic refrigeration system are shown in Figure 85-1. They include the compressor, condenser, metering device, and evaporator. Also shown are some of the important accessories common to commercial refrigeration systems: a high/low pressure control, condenser fan, receiver tank, suction to liquid-line heat exchanger, filter drier, evaporator fan, thermostat, and suction-line accumulator. Each of these accessories helps maintain an efficient system.

Refrigeration systems require the addition of components not normally found on air-conditioning systems.

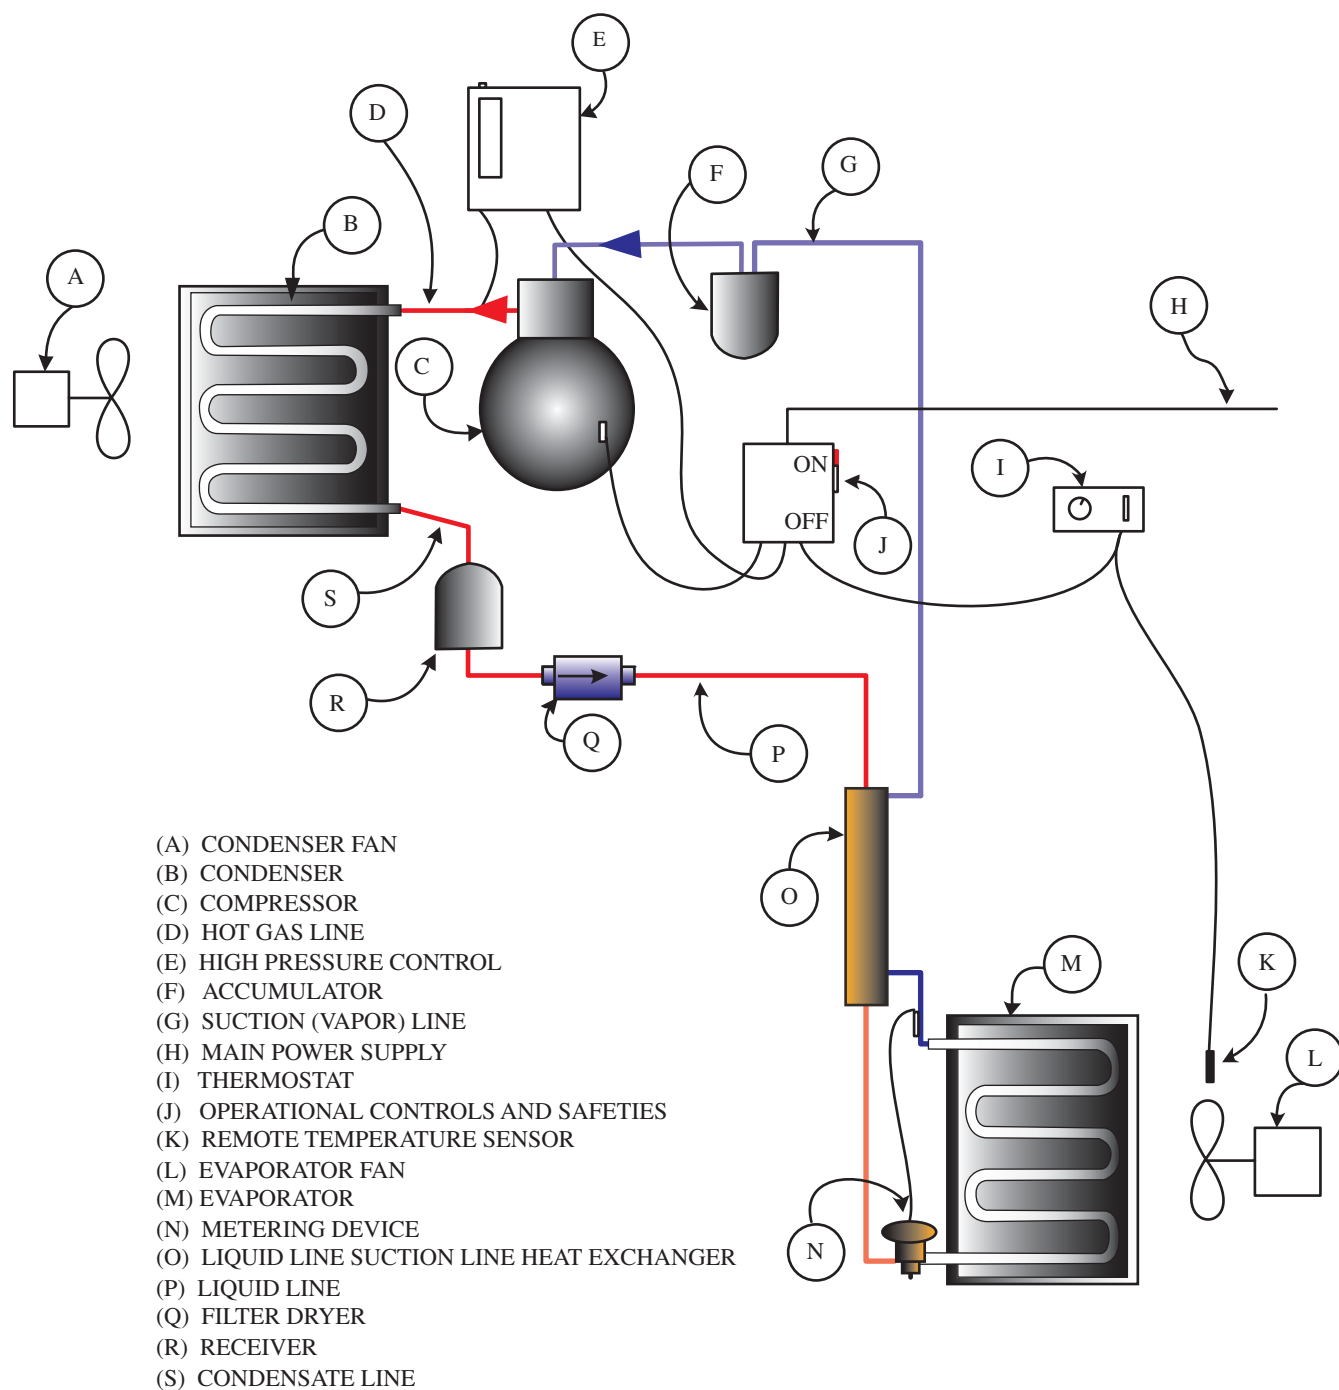

Figure 85-1 A simple refrigeration system with a single compressor and air-cooled condenser.

Each of these devices that are added will create resistance to the flow of liquid or vapor refrigerant. Such resistance reduces the overall operating efficiency of a system. For that reason, technicians must exercise good judgment when deciding whether to add additional accessories to an operating refrigeration system. They must weigh the advantages and necessity for such accessories to the proper operation of the system as compared to any detrimental effect it has on system capacity. This is of prime concern with systems that are marginally meeting current demand.

85.4 MULTIPLE-EVAPORATOR SYSTEMS

Multiple-evaporator systems are common in supermarkets. Multiple evaporators make it possible to use a single compressor to control a number of different case or fixture temperatures. Figure 85-2 shows a three-temperature system.

Evaporator pressure regulators (EPRs) are placed in the suction lines to the two higher temperature evaporators. These are adjusted to maintain the desired evaporator temperature.

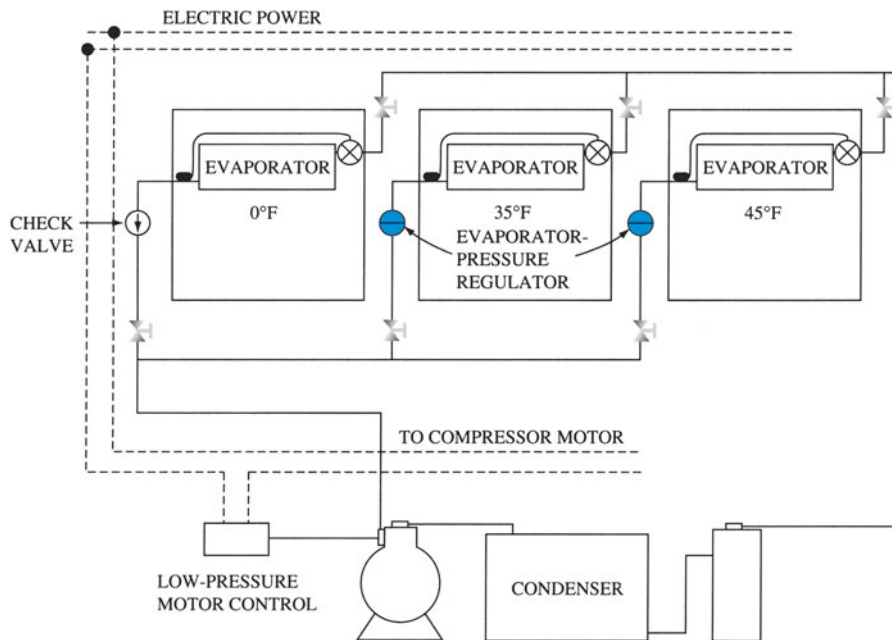

Figure 85-2 Multiple-evaporator system using evaporator pressure regulators to maintain different conditions in each box.

A check valve is installed in the suction line from the lowest-temperature coil. This prevents migration of the refrigerant from the higher-temperature coils to the low-temperature coil when the compressor is producing cooling for the higher-temperature coils.

When all of the coils require refrigeration, such as on start-up, the compressor will operate at the suction pressure required to cool the highest-temperature coil first, then the middle-temperature coil, and, last, the low-temperature coil. The compressor must be sized to produce the entire cooling load at the evaporator pressure of the lowest-temperature coil. The low-temperature coil will receive very little refrigeration until the higher-temperature coils are satisfied. For this reason, the load on the low-temperature coil must account for 60 percent of the total load, otherwise it may not receive adequate refrigeration.

On a small system it is general practice to install a surge tank in the suction line of the low-temperature evaporator to prevent short-cycling.

SERVICE TIP

Restaurants come and go, but the refrigeration equipment stays behind. Frequently, refrigeration equipment designed for the original restaurant may not meet the needs of the new operation. When the primary loads change, it is not possible simply to make adjustments to multiple-evaporator systems to accommodate these changes. It is not possible to simply turn down or up the low-temperature side of a system without adversely affecting the medium- or high-temperature side of a system. Restaurant managers are not always aware of this issue. It is in your best interest to take the time to explain to the manager what the difficulties can be for changing the load for refrigeration systems.

85.5 EVAPORATOR TEMPERATURE CONTROLS

Evaporator temperature can be controlled with a conventional thermostat, a suction pressure cutout control, or an evaporator pressure regulator. If the evaporator coil temperature is excessively low, the food stored in the space will be robbed of moisture and dry out. This is particularly true of vegetables and fruits. This moisture collects on the evaporator coil where it will freeze and lead to a buildup of ice.

An EPR maintains a steady refrigerant pressure in the evaporator coil. Since both liquid and vapor refrigerant fill the evaporator coil, the refrigerant is in its saturated state. For any given preset refrigerant pressure there will be a corresponding refrigerant saturation temperature. Regulating for a constant evaporator pressure provides a stable evaporator temperature.

Conventional thermostats and suction pressure cut-out controls do not always maintain a constant evaporator pressure like an EPR. With these types of controls, the evaporator pressure is most likely to fall with a decrease in load. This can result in a lowering of the coil temperature to undesirable levels.

85.6 MULTIPLE-COMPRESSOR SYSTEM

Where the refrigeration load varies over a wide range, such as in supermarkets, it is desirable to use multiple compressors connected in parallel, as shown in Figure 85-3. Suction pressure control is used to turn on and off individual compressors as required to match the load (Figure 85-4). These controls also have the ability to change the lead compressor to obtain approximately equal running time on each compressor. A single condenser and receiver are used for all units.

The refrigerant piping must be done properly, as shown in Figures 85-5 and 85-6. Referring to Figure 85-5,

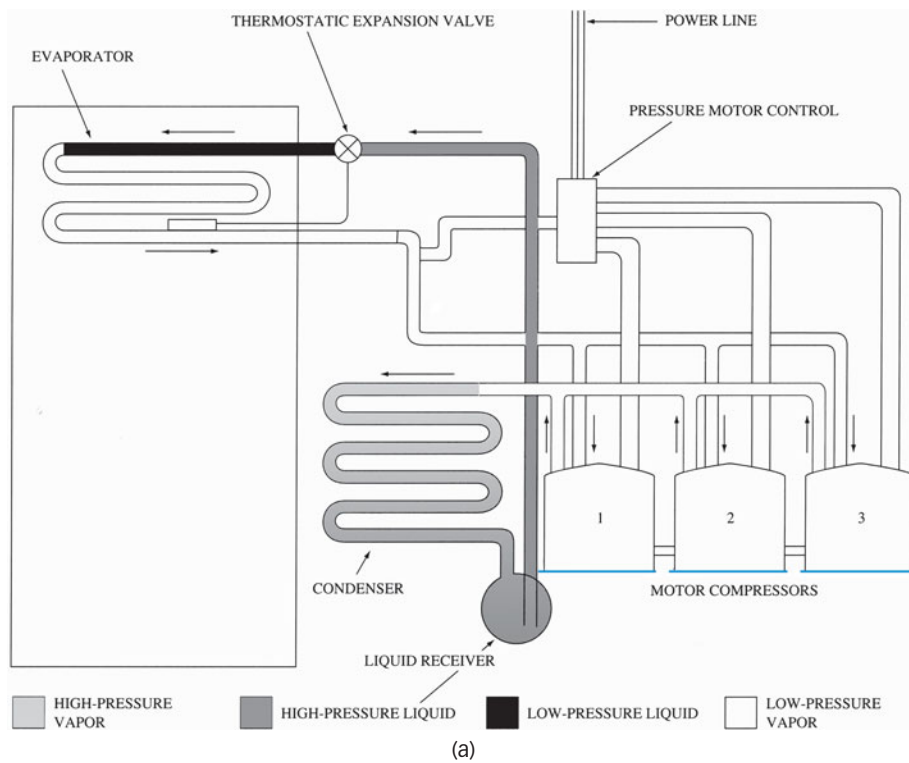

Figure 85-3 (a) Diagram of a multiple-compressor system using three compressors connected in parallel; (b) multiple-compressor rack.

Figure 85-4 Multiple-compressor control panel.

Figure 85-5 Suction-line piping for parallel compressors.

Figure 85-6 Discharge-line piping for parallel compressors.

the suction piping should be brought in above the level of the compressor. With multiple compressors, a common suction header should be used and the piping should be designed so that the oil return to several compressors is as nearly equal as possible.

If an oil-level control is not used, the discharge piping, as shown in Figure 85-6, should be used with the discharge piping running to a header near to floor level. With this arrangement, a discharge line trap is not required since the header serves this purpose.

CAUTION

Maintaining the proper oil level between multiple compressors is critical. If the compressor oil level drops, the system can be severely damaged or destroyed. Compressors have oil safety switches that are designed to trip and take the compressor offline when the oil pressure drops below a critical level. However, system owners and managers frequently see oil trips as a “nuisance” call and will push the reset button themselves. It is important that you stress to your customers that you must be notified each and every time a system shuts down as a result of an oil problem so that you are able to identify the root cause of the problem and correct it.

Pressure in the reservoir is reduced by boiling the refrigerant contained in the oil and relieving the pressure above the oil through a vent line to the suction header. An oil-level control meters the oil to the compressors equal to the pumping rate and thereby maintains the oil level specified by the manufacturer.

TROUBLESHOOTING

Oil is returned to a compressor as a result of the velocity of refrigerant vapor in the suction line. If an evaporator defrost system is not working correctly, then the evaporator will

Figure 85-7 Walk-in freezer.

ice over, resulting in a slower flow of refrigerant vapor. This can result in oil slugging of the evaporator. If the oil level in an entire system appears to be low, do not simply add oil. Look for the primary cause of the oil shortage. Refrigerant oil does not simply evaporate. It stays in the system somewhere, and it is important that you locate it and determine what is necessary to have it return to the compressor during system operation.

85.7 WALK-IN REFRIGERATORS AND FREEZERS

Walk-in coolers and freezers are one of the most common applications for commercial refrigeration (Figure 85-7). Their cabinets are normally made with modular insulated metal-clad panels, usually 1–4 in thick, depending on the temperature requirement inside the cabinet. Using corner sections and standard wall and ceiling panels can make various-sized boxes, as shown in Figure 85-8. Panels can be assembled

Figure 85-8 Modular walk-in cooler/freezer.

Figure 85-9 (a) Aluminum cabinet exterior; (b) stainless steel cabinet exterior.

on the job using special eccentric cam fasteners. Insulated panels are used for the floors. The interior surfaces of wall and ceiling panels are usually clad with aluminum and floors with galvanized iron. Stainless steel is also commonly used both outside and inside the cabinet (Figure 85-9).

Occasionally one structure will contain both a cooler and a freezer. Normally the freezer door is located in the cooler compartment. This makes the overall system more economical, since a common wall is used. Also it allows less heat to enter the freezer when its door is opened.

CAUTION

Local, state, and federal laws require that all walk-in refrigerators and coolers have safety latches that can be opened from the inside. It is a good practice when working alone to confirm that the latch is operating properly so that the door can be opened easily from the inside. There may also be a safety indicator visible from the outside (Figure 85-10).

Figure 85-10 Safety indicator light located on the outside of a walk-in freezer.

(a)

(b)

Figure 85-11 (a) Drop in unit sits on top of cabinet (Courtesy of Danfoss); (b) controls located outside the walk-in for a refrigeration system located in an equipment room.

The refrigeration system for these cases can be either remote built-up systems or packaged systems that drop in place (Figure 85-11). Remote systems can have their condensing unit located in the building either near the walk-in unit or in an equipment room. The condensing unit can also be installed outdoors. When located outdoors, special controls are added to allow it to operate in low ambient temperatures.

Each time the door is opened, warm air enters the case. To prevent some of this warm air from entering the case, some systems will have a door switch, (Figure 85-12),

Figure 85-12 A door switch used on a walk-in freezer.

Figure 85-13 A condensate drain line connected to an evaporator.

which will shut off the fans when the door is opened. This door switch may also control a liquid-line solenoid, which stops the flow of refrigerant to the evaporator each time the door is opened. Some cases may also install a door curtain to help inhibit this warm air from entering the case.

Evaporator condensate lines normally connect to a drain outside of the cabinet. Slope the line $\frac{1}{4}$ in per foot for proper drainage. Install a trap so outside air does not enter the cabinet. Figure 85-13 shows a typical condensate installation. Heat the lines if they are subject to freezing temperatures, such as inside a freezer. Drain-line heaters inside the cabinet are always energized. Drain-line heaters outside the cabinet are thermostatically controlled and only energized when needed.

85.8 DEFROST SYSTEMS

Since most refrigeration systems operate at evaporating temperatures below 32°F, frost will accumulate on the evaporator's surface. This frost must be removed on a regular basis, otherwise it will begin to insulate the surface of the evaporator and prohibit the transmission of heat from the product to the refrigerant within the evaporator.

There are different methods by which an evaporator can be successfully defrosted. The method used will depend on the system application. For most medium-temperature applications, the air within the case can be used to successfully defrost an evaporator. At regular intervals, the compressor is shut down and the evaporator fan(s) will continue to draw air across the evaporator, warming the coil and melting any frost. The number of times the compressor is cycled off and the length of time the compressor stays off will vary. The condition of the environment surrounding the case will determine if more or less time is needed. If the case is located in a very humid location, it will require more time for defrosting.

For low-temperature applications, the case air is too cold and cannot be used to defrost the evaporator, so a supplemental heat source must be added. There are two methods commonly used. One method de-energizes the compressor and energizes a resistive-type heater, which is

attached directly to the evaporator coil. The electric heaters stay energized and the compressor stays de-energized until the frost is removed from the coil. Another method is to introduce discharge vapor from the compressor directly into the evaporator and use this heat to melt the frost from the evaporator. The discharge vapor from the compressor will continue to directly enter the evaporator until the frost is melted.

When electric resistive-type heaters are used (Figure 85-14), they are mounted on the outer surface of the evaporator's coils. These resistive heaters are sized to provide

Figure 85-14 (a) Electric defrost heater diagram; (b) evaporator fins and electric heater strips; (c) (see next page) electric heater strips held in place by wire clips.

(c)

Figure 85-14 (Continued)

sufficient heat to effectively defrost the coil. Their capacity is normally rated in watts per foot. They are shaped to fit snugly onto the coil surface, creating an efficient heat transfer. Most heaters are manufactured for a specific coil, and when replacing these heaters it is best to obtain the original equipment manufacturer (OEM) replacement. There are universal defrost heaters available, but matching their wattage and shape may be very difficult at times.

A defrost timer is used to control the defrost operation. A typical mechanical defrost timer is shown in Figure 85-15. It initiates the defrost cycle, controls the operation of the compressor and defrost heaters, and is part of the defrost termination. Defrost timers can be adjusted to defrost once a day or several times a day. Screw-fastened pins are located at positions around the 24-hour clock dial. As shown in Figure 85-16, the pins are located at 6 AM and 6 PM. The inner knob adjusts the total defrost time anywhere from 2 to 110 minutes.

The number of defrosts per day depends on case location. Freezers are usually designed to defrost once or twice a day. The more humid and warm a location is, the more defrosts it will need. If a system needs to be defrosted more frequently,

**Figure 85-16** Mechanical defrost timer can be set for number of defrost cycles, time of cycle, and duration of cycle.

add only one additional defrost period at a time and monitor the results. Avoid adding too many defrost periods—it may not be beneficial to the system or to the customer.

Figure 85-17 illustrates a common wiring diagram and the instructions for an electric defrost system. As the diagram indicates, the time motor is energized continuously. The normally closed contacts 2–4 of the defrost timer are wired in series with the compressor and the evaporator fan motor. The normally open contacts 1–3 are wired in series with the electric defrost heaters and the timer-release solenoid (TRS). The timer motor controls the operation of contacts 2–4 and 1–3. They work opposite each other. When contacts 2–4 are closed, 1–3 are opened. When contacts 2–4 are opened, 1–3 are closed. When the timer motor initiates a defrost, contacts 2–4 will open and 1–3 will close. This will stop the compressor and the evaporator fan motor and energize the defrost heaters (Figure 85-18).

A defrost cycle is typically terminated based on either coil temperature or low-side pressure. Most defrost timers will also have a failsafe time that can be set to terminate defrost based on time. On systems being terminated by a pressure or temperature switch, if the termination switch fails, the defrost will be terminated by time. The failsafe time should be set long enough to allow the system to terminate by the temperature or pressure switch and short enough to prevent the system from over defrosting or creating a hazardous condition. Usually the failsafe time is set to 35–45 minutes.

Terminating a defrost cycle by temperature is the most popular method. A temperature switch, such as one shown in Figure 85-19, is used to terminate a defrost cycle. It is installed on the evaporator at a location where the design engineers feel that frost will leave the coil last. The temperature switch may have a range and differential setting. The settings shown in Figure 85-20 are for a walk-in freezer that operates at 0 °F. The range and differential are set at approximately 30°F and 24°F, respectively. With these settings, the defrost cycle would terminate when the evaporator temperature at the switch location reaches approximately 30°F.

**Figure 85-15** A typical defrost timer for a walk-in freezer.

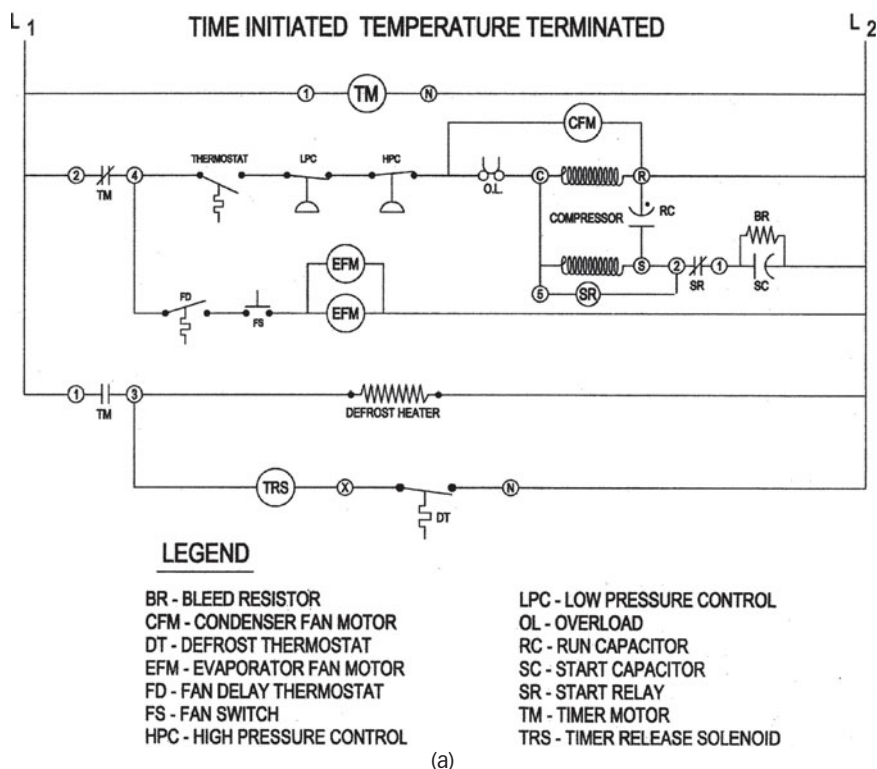

Figure 85-17 (a) A wire diagram for an electric defrost system; (b) instructions for setting the defrost timer.

Figure 85-18 Evaporator fans stop during the defrost cycle.

Figure 85-20 Range and differential settings for a temperature termination switch on a freezer.

Figure 85-19 Adjustable temperature termination switch.

At this specified temperature the defrost termination switch will close and energize the timer release solenoid (TRS), switching the system back into the refrigerating mode. The TRS is an electric solenoid located in the defrost timer. When the TRS is energized, it will mechanically switch the timer contacts: 2-4 will close and 1-3 will open. The defrost cycle will not initiate again until the temperature reaches the range setting minus the differential setting. In this case, this is 6°F: 30°F - 24°F = 6°F. Many temperature termination switches are not adjustable, and the temperature at which the switch closes may vary from design to design. It is best to check with the manufacturer of the system to determine the correct temperature setting. Some defrost termination switches will have the setting stamped onto the body of the device.

When the defrost cycle is terminated by pressure, a pressure control is used as the defrost termination switch. When the control senses a low-side pressure that will ensure that all of the ice is removed from the evaporator, it will close and terminate the defrost cycle. Many times the pressure control and the defrost timer are combined into one unit. The pressure at which the switch closes will depend on the type of refrigerant used in the system. Check with the manufacturer for the recommended pressure setting.

The defrost timer can also be used to terminate defrost by time, although this method is not very popular. The time required to defrost an evaporator will vary depending on how much frost has developed on the coil. The ambient humidity level and the usage of the case will be factors in how much frost develops on the coil. If the case is in a very humid location with heavy usage, a heavy accumulation of frost will develop on the coil. If the case is installed in a location where the humidity level is low and has very little usage, the frost that develops on the coil will be less for the same timespan.

Defrost systems can run into two problems: the system will be either over-defrosted or under-defrosted. Over-defrosting is when the defrost heaters stay energized too long, causing the case temperature to rise too high. The product may begin to melt and then refreeze. This problem can be identified by monitoring the box temperature during defrost or by examining the product in the case. Ice crystals forming on frozen product may be a sign of over-defrosting. Over-defrosting is normally caused by a malfunction in the termination of the defrost cycle. For time termination defrost systems, either the defrost time is set too long or the time clock is defective. On pressure-terminated systems, either the terminating pressure control is set too high, the pressure control is defective, or the solenoid coil in the defrost timer is incorrectly wired or defective. On temperature-terminated systems, either the temperature control is set too high, the control is defective, or the solenoid in the defrost timer is defective.

Systems that are under-defrosting will result in a frozen evaporator. The frost that normally develops on the evaporator coil will continue to build until the entire surface of the evaporator is iced over. This can be caused by a defective or incorrectly set time clock that does not initiate a defrost cycle. Or it can be caused by an open heater element or a defective defrost termination switch that continually terminates the defrost on each initiation of a new cycle.

Sizing Walk-in Coolers and Freezers

Sizing walk in coolers and freezers can be complicated because of the many factors involved. To simplify this process, there are many reference charts available that list the required refrigeration loads for different size walk-ins. Generally they provide two load estimates—one for average usage and one for heavy usage. It is important to remember that these load calculations are only estimates and the actual load requirements for a particular walk-in cooler or freezer may be different.

Heat-load calculations for any walk-in cooler or freezer are based on four separate loads:

- Heat transmission, which is the heat gained through the walls, floors, and ceiling of the walk-in structure

- Air infiltration, which is heat gained due to the air entering the structure
- Product load, which is the heat removed from a product to cool it from one temperature to a lower temperature; also includes the heat of respiration from fruits and vegetables
- Supplemental loads, which are made up of the heat dissipated by people or mechanical equipment in the walk-in

When sizing a walk-in cooler or freezer, a technician and/or salesperson must understand the application and environment in which the walk-in will be used. There are several situations where a person relying on the sizing chart alone could miscalculate the actual load for the walk-in.

If, for example, the walk-in were to be located outdoors rather than indoors, the heat gain through the walls would be much greater in the hot days of the summer than normally accounted for in many sizing charts. The size of the refrigeration equipment may need to be increased to remove this additional load. Two important questions a person sizing a walk-in cooler or freezer should ask are, Where is the walk-in going to be installed? and What will the maximum ambient temperature outside of the box be?

Other important questions to ask concern the product going into the walk-in: How much and what type of product will be stored? What is the initial temperature of the product entering the walk-in? At what temperature does it need to be stored? Again, most charts are based on averages. If the temperature of the product entering the walk-in is higher than normal or if an unusual amount of product will be stored in the walk-in, the capacity of the refrigeration equipment may need to be increased. It is not unusual for the load from the product to exceed all other loads added together.

Another potential problem with using generic sizing charts is with the supplemental loads. If the supplemental load is higher than the averages, then the capacity as listed on a generic chart may need to be increased. For example, if many people will be working in the walk-in cooler, or if some type of major equipment will be running in the walk-in on a consistent basis, the load may need to be increased to handle this additional load.

There are other instances that may cause the actual load requirements to differ from the load as shown on a basic chart. Any person sizing walk-in coolers and freezers should know the process of calculating the actual load on a walk-in box. This will allow them to determine if a particular application falls outside the loads as stated on the charts and if a complete load calculation needs to be done.

85.9 REFRIGERATION EQUIPMENT SELECTION

Many field-assembled refrigeration system installations require the installing contractor or sales engineer to select the proper system components. This involves selecting the correct condensing unit (compressor), unit cooler (evaporator), metering device, refrigerant, accessories, and piping. Before any of the system components can be selected, determine the required system BTU capacity by referring to a sizing chart or performing a heat-load calculation. Knowing

the required BTU capacity for the project is the baseline for selecting the proper components for any installation. Many of the major system components are selected based on the BTU capacity of the system.

Normally, the first major system component selected is the condensing unit, or compressor if the system will have a remote condenser. The BTU capacity of any compressor or condensing unit is based on the suction pressure of the refrigerant entering the compressor. Because of this, most manufacturers will provide the BTU capacity of their compressors or condensing units at a specific entering suction pressure or, more correctly, at a specific saturation temperature.

Determine the refrigerant saturation temperature by using a standard pressure/temperature (PT) chart and convert the suction pressure to its equivalent saturation temperature. For example, if HFC-134a is the refrigerant and the entering suction pressure is 18.5 psig, the corresponding saturation temperature entering the compressor would be 20°F. Next determine the design evaporator temperature to determine the required saturation temperature entering a compressor. Many standard medium-temperature applications use an evaporator temperature of 20°F–25°F, and many low-temperature applications use an evaporating temperature of –10°F. Once the design evaporator temperature is determined, subtracting any suction line pressure losses will allow the approximated saturation temperature at the inlet of the compressor to be determined. For most applications, a pressure loss equivalent to a 2°F reduction in saturation temperature is used. For example, if the design evaporating temperature were 22°F, the assumed saturation temperature entering the compressor would be 20°F.

The next component selected is the unit cooler or evaporator. The unit cooler must closely match the design BTU capacity of the compressor or condensing unit. Manufacturers of unit coolers will provide their BTU capacity at a specific temperature difference (TD), which is the difference between the air entering the unit cooler and the evaporating temperature of the refrigerant leaving the unit cooler. The desired TD of the unit cooler is selected to match the humidity requirements of the product being stored. For storage of general packaged products at a relative humidity of 85 percent, a TD of 10°F is normally used. Other types of products may require different relative humidity conditions, which will change the design TD. See Unit 18 for more information on evaporator temperature drop and humidity control.

Once the unit cooler has been selected, the metering device is next. Most field-installed systems will use a thermostatic or electronic expansion valve. Capillary tubes and automatic expansion valves are normally used on self-contained systems that are completely assembled at the factory. The thermostatic expansion valve (TEV) is also selected based on the BTU capacity of the system. It is chosen to closely match the BTU capacity of both the condensing unit and unit cooler. The capacity of a TEV is based on several system characteristics. Always follow the selection guidelines of the TEV manufacturer for their recommendations. See Unit 17 for more information on TEV sizing.

Once all the major system components have been chosen, select the ACR tubing size. Size the tubing based on the BTU capacity of the system as well as the length of run. It is important to use correctly sized suction, discharge, and liquid lines on any application. Using an undersized suction line reduces overall system capacity. Using an oversized suction line

leads to oil return problems. Always follow the equipment component manufacturer's guidelines for their recommendations. See Unit 26 for more information on refrigerant piping.

85.10 LOCATING AIR-COOLED CONDENSING UNITS

When installing walk-in coolers and freezers, the installing contractor will need to select the proper location of the condensing unit, such as shown in Figure 85-21. Location is an important consideration for the overall success of the installation. There are several items to consider when selecting the location of this type of condensing unit.

First, the location should be discussed with the customer. Be sure the customer is in agreement with the placement of the condensing unit. The customer may have a plan for the location different from where the installing contractor decides to place the unit. As retail space becomes more expensive, customers will want to take advantage of all the indoor space and may want the condensing unit located outdoors or in an indoor location that will not interfere with the retail operation.

If the condensing unit is to be placed indoors, make sure the location has adequate ventilation. Low-temperature condensing units will require approximately 200 CFM per 1,000 BTU, and medium-temperature units will require approximately 165 CFM per 1,000 BTU. Always check with the condensing unit manufacturer for ventilation requirements, as they may differ from these approximate values. Another consideration with air-cooled units located indoors is the heat they may add to the space. This additional heat may be objectionable to the equipment owner.

An alternative to locating the condensing unit indoors is to place it outdoors. When installing outdoors, there are several additional components that should be installed on the condensing unit. The condensing unit should have a crankcase heater installed. This will help to prevent refrigerant migration during the off cycle when the condensing unit is exposed to temperatures that are colder than the evaporator. The condensing unit will also need some means of keeping the high-side pressure above a minimum value during periods of low outdoor temperatures. This is normally accomplished with either a fan cycling control or a head pressure controller.

Figure 85-21 Air-cooled condensing unit.

Figure 85-22 Outdoor condensing unit with enclosure.

The method of controlling the case temperature may also need to be modified. The system should use a pump-down method to control the operation of the condensing unit. A standard air-sensing temperature controller should be used to control the operation of a liquid-line solenoid. When the temperature controller is satisfied, it will close the liquid-line solenoid, causing the refrigerant to be trapped in the condenser and receiver. This will cause the low-side pressure to drop. The system's low-pressure control will then shut down the condensing unit when the low-side pressure drops to an appropriate value.

The outdoor unit should also be covered to protect it from the outdoor environment, as shown in Figure 85-22. If the condensing unit is ordered for an outdoor application, it will normally come with some type of enclosure. When moving an indoor condensing unit to the outdoors, make sure an adequate enclosure is constructed to properly protect the unit.

85.11 INSTALLING EVAPORATOR COILS IN A WALK-IN COOLER OR FREEZER

When installing a walk-in cooler or freezer, the installation of the evaporator coil is vital to the proper operation of the entire refrigeration system. A typical installation of an evaporator coil is shown in Figure 85-23. There are several general guidelines that apply to most installations; however, it is always best to check with the manufacturer of the evaporator for specific instructions. Below is a list of several guidelines:

- The air pattern of the evaporator must envelop the entire case. This is important to provide a more uniform temperature throughout the entire box. Do not install the coil where product could potentially be stacked that would block the airflow. Always allow for sufficient space between the rear and sides of the evaporator to permit free return air.
- Never install an evaporator above a door. This can cause the evaporator to draw warm, humid air through the coil each time the door is opened. This will cause the evaporator to frost up more quickly and may cause an icing problem.

Figure 85-23 An installation of an evaporator coil in a walk-in cooler.

- Do not install an evaporator coil in an area where it will interfere with the cooler's aisles or storage racks. This may cause a problem for the storeowner, which could result in the evaporator needing to be relocated. The location of the evaporator should allow for easy storage and removal of the refrigerated product.
- The evaporator should be installed in a location that will provide the shortest possible distance between it and the condensing unit. Excessive piping can increase the pressure drop between the evaporator and the condensing unit. An excessive pressure drop will decrease the system's overall refrigeration capacity.
- The location of the condensate drains should provide for minimum pipe length. This will allow for proper drainage. In addition, the unit should be kept level for proper drainage, and it should be trapped. When draining two or more evaporators into a common drain, always trap drain lines individually to prevent vapor migration. On low-temperature evaporators, the traps should be located outside the case. If freezing of the traps is still a potential problem, they should be heated and wrapped.
- Supports for hanging the unit should be sufficient to hold its weight. For coils up to 250 lb, $\frac{5}{16}$ -in bolts or threaded rods should be sufficient. For coils up to 500 lb, $\frac{3}{8}$ -in bolts or threaded rods should be used. Coils over 500 lb should use $\frac{5}{8}$ -in bolts or threaded rods. When using rod hangers, allow adequate space between the top of the unit and the ceiling for cleaning. If fastening the evaporator flush to the top of the cooler, seal the joint between the top and ceiling with an approved sealant.

Other considerations include mounting of the TEV sensing bulb and the liquid-line solenoid thermostat sensing bulb. The expansion valve bulb will be attached at an appropriate location and in direct contact with the evaporator coil. The bulb will be wrapped with insulation. Figure 85-24 shows the pressure and bulb sensing lines for an externally equalized TEV.

The liquid-line solenoid thermostat sensing bulb is often installed alongside the sensing bulb used to display the walk-in temperature (Figure 85-25). They should be located

Figure 85-24 Pressure- and temperature-sensing lines for an externally equalized TEV.

Figure 85-25 Walk-in temperature display located outside the cabinet.

at a position in the walk-in to measure the average temperature of the cabinet. They should not be located near the door. It is good practice to shield the sensing bulbs so they do not accidentally become damaged and to seal the points of entry into the cabinet (Figure 85-26).

Figure 85-26 Sensing bulbs should be protected from accidental damage and points of entry; sensing lines penetrating through the walk-in wall should be sealed.

UNIT 85—SUMMARY

There are many types of commercial refrigeration systems designed for meeting the requirements of specific applications to maintain the quality of the product at minimal expense while meeting current laws and regulations regarding the environment. One way to classify these different systems is to categorize them by the four broad based areas of high, medium, low, and cryogenic evaporator coil temperatures.

Single-component systems will cool just one space, while multiple-evaporator systems commonly found in supermarkets will utilize a single compressor to control the temperature for any number of different spaces. In many of these systems, regulator control valves for evaporator pressure are used to maintain the desired evaporator coil temperatures. Multiple-compressor arrangements can be utilized for conditions where the load may vary considerably. The compressors can cycle on and off as the load dictates.

WORK ORDERS

Service Ticket 8501

Customer Complaint: Ice Buildup on Evaporator

Equipment Type: Supermarket Walk-in Cooler

The service technician meets with the produce manager of the supermarket who describes a problem with one of the walk-in coolers. The evaporator coil exterior is covered in ice and the temperature of the space has begun to gradually increase. The technician asks what type of produce was being stored in the space, realizing that some foods give off considerable amounts of moisture that collects on the evaporator coil.

At the door to the walk-in cooler, the technician carefully checks the door seals to make sure that air is not being drawn into the space. The technician also asks the produce manager if the door has been left open for long periods of time. The technician then checks the automatic timer defrost controls, which are operating properly. The coils are normally defrosted by electric strip heater elements that are now completely covered in ice. The drain line out of the space from the drip pan is protected with electric heat tape that feels warm to the touch.

The technician then decides to check the refrigerant controls. The space has a thermostatic expansion valve, a box solenoid valve, and an evaporator pressure regulator (EPR). The box solenoid valve is energized and open as it should be due to the high space temperature. The technician then notices that the pressure gauge attached to the EPR is reading very low. Looking closer, the technician finds that the bypass valve around the evaporator pressure regulator has been left open. The technician closes the bypass valve and the evaporator

coil pressure immediately begins to rise. Evidently, the last time the system was pumped down, the EPR bypass was left open.

Service Ticket 8502

Customer Complaint: Compressor Tripping Out

Equipment Type: Supermarket Multiple-Compressor System

The service technician meets with the produce manager of the supermarket, who describes the problem. One of two compressors has tripped out on low lube oil pressure, and its oil level appears low. The compressors are being operated in parallel to cool six different spaces. The one operating compressor is having difficulty maintaining the load by itself, and the space temperatures are beginning to slowly rise.

The first thing that the technician does is check to see if the compressors are equipped with oil separators on the discharge side. Upon investigation, the technician suspects that the float inside the oil separator on the idle compressor has failed and the oil is not returning to the crankcase. The technician will have to order a new separator and expects this will take a few days to arrive.

In the meantime, the technician needs to bring the space temperatures back down to normal. This is accomplished by bypassing the faulty oil separator and then adding oil to the compressor. However, now the compressor can no longer be operated in parallel without an oil separator. The technician changes over the valve configuration so that the two compressors are split. Each compressor will be lined up to separately cool three of the six spaces. Once the new separator arrives, the faulty one will be replaced and the system will be once again lined up for parallel operation.

Service Ticket 8503

Customer Complaint: System Is Not Defrosting

Equipment Type: Walk-in Freezer

A technician is called out to service a walk-in freezer operating at a temperature of 28°F and climbing. The walk-in freezer uses R-404a refrigerant, a semihermetic compressor, a thermostatic expansion valve, an air-cooled condenser, and a time-initiated, temperature-terminated defrost method.

When the technician arrives on the job, the evaporator's coils are completely covered in ice and the evaporator fans appear to be running normally. After further investigation, the technician observes the following conditions:

- An operating suction pressure of 20 psig
- An operating discharge pressure of 229 psig
- No bubbles in the liquid-line sight glass
- A 95°F air temperature leaving the condenser

A manual defrost is initiated and the following conditions are observed:

- The evaporator fans shut down.
- Current draw of 5 A is measured through the defrost heaters.
- Defrost heaters stay energized for 35 minutes and then the defrost cycle terminates.
- The evaporator fans turn back on after a delay.
- After running for 20 minutes, the case temperature starts to drop below 20°F.

Based on these observations, the technician determines that the defrost timer must be replaced.

UNIT 85—REVIEW QUESTIONS

1. What are three important items to consider in the design of commercial refrigeration systems?
2. Refrigeration is divided into four broad areas based on the evaporator coil temperature. What are these?
3. Food items like milk, cheese, and fresh fruit and vegetables are usually stored at what temperatures?
4. Medium-temperature refrigeration coil temperatures ranging from 32°F down to 0°F are generally used for what applications?
5. A deep freeze would be an example of what coil temperature application?
7. List the essential components required for a basic refrigeration system.
8. List the important accessories common to commercial refrigeration systems.
9. What type of system makes possible using a single compressor to control a number of different case or fixture temperatures?
10. What would be installed in the suction line from the lowest-temperature coil in a multiple-evaporator system?
11. List the three ways that evaporator temperature can be controlled.
12. What type of system would be used when the refrigeration load varies over a wide range, such as in a supermarket?
13. Explain a method used on walk-in coolers and freezers to help prevent warm air from entering the case when the door is opened.
14. Why do commercial refrigeration systems need a defrost system?
15. List the ways an evaporator can be defrosted.
16. What are the three methods by which a defrost cycle can be terminated?
17. List some of the loads that must be considered when sizing the BTU requirements of a walk-in cooler or freezer.
18. What are the four separate loads used to calculate the heat load for walk-in coolers or freezers?
19. What is the first step in selecting commercial refrigeration equipment for new installations?
20. What are the approximate ventilation requirements for air-cooled condensing units located in an indoor environment?
21. When locating an air-cooled condenser outdoors, why must the system be modified?
22. List at least three requirements when installing an evaporator coil in a walk-in cooler or freezer.

UNIT 86

Supermarket Equipment

OBJECTIVES

After completing this unit, you will be able to:

1. explain the difference between multiplex, distributed, and secondary-loop systems.
2. explain the purpose, arrangement, and components of compressor racks.
3. sketch a simple hot-gas defrost system layout.
4. troubleshoot open refrigerated display cases.
5. explain the difference between series, parallel, and hydronic heat-reclaim systems.
6. Describe how basic CO₂ cascade refrigeration systems operate.

86.1 INTRODUCTION

Energy-efficient designs are at the forefront of today's advanced supermarket refrigeration systems. Traditional multiplex direct-expansion (DX) systems require very large refrigerant charges and consume substantial amounts of electrical power. In addition, these systems require long lengths of refrigerant piping, which can lead to significant refrigerant losses. New designs such as distributed, secondary loop, low-charge multiplex, and advanced self-contained refrigeration systems are replacing the traditional multiplex DX systems. Many of these newer designs use less energy and have reduced amounts of refrigerant. New types of condenser and evaporator multichannel- and microplate-type heat exchangers are being designed to reduce the total refrigerant charge required by the system.

There is some movement toward using more nontraditional refrigerants such as CO₂. This is because many of the newer ozone-friendly refrigerants have relatively high global warming potentials. Refrigerant such as CO₂ has drawbacks because of the high operating pressures it requires, but CO₂ has the ability pound per pound to absorb a lot of heat and has no impact on the ozone. There are over 500 supermarkets in Europe that are currently using CO₂ refrigeration systems.

Waste-heat-recovery improvement is also one of the main priorities for new supermarket design. Heat-reclaim systems have been in use for some time now, but today's advanced systems are utilizing secondary loops and water-source heat pumps to gain maximum efficiency. The use of heat pumps allows for a large amount of the rejected heat to be reclaimed without increasing the discharge (head) pressure like traditional systems. Lower head pressure results in reduced power consumption. Advanced supermarket refrigeration systems with waste-heat recovery can substantially reduce the combined refrigeration and HVAC energy use and are becoming increasingly more commonplace. These systems are being designed to minimize the total equivalent warming impact.

86.2 "TRADITIONAL" SUPERMARKET LAYOUT

A typical supermarket layout is shown in Figure 86-1. The most common refrigeration system used in "traditional" supermarkets is the multiple DX (multiplex) system. The compressors are located in a machine room near the back of the store or on the roof. Heat rejection is usually accomplished with air-cooled condensers because they are the easiest to maintain. Refrigerant is piped from the discharge of the compressor to DX coils located within the cases and then back again (Figure 86-2).

Some supermarket systems will be designed to use a single compressor for each refrigerated case. Others are designed to use multiple refrigerated cases connected to a single compressor. Still other supermarkets may use a rack of multiple compressors (rack systems) piped together and connected to multiple refrigerated cases. This rack-type system is the most common configuration for multiplex DX systems.

Compressor Racks

Most often there are multiple racks that serve a number of cases that are operating at different temperatures. As an example, there may be a 15°F rack, a 20°F rack, and a -25°F rack (Figure 86-3). The use of individual racks allows the refrigerant temperature in the case evaporator coil to be close to the case operating temperature. This is accomplished with a rack suction pressure controller, which will indirectly control the refrigerant temperature for the rack.

Most racks utilize more than one compressor, usually three to five (Figure 86-4). There is an efficiency advantage to having multiple parallel compressors, sometimes of different capacities (called an uneven rack system). This is because supermarket systems must be designed for full-load operation even though the actual average load is generally below the peak load. This design peak load might only be reached on a few very hot days in the summer. Therefore, a rack with just one large compressor would be required to operate unloaded or cycle on and off frequently. Producing

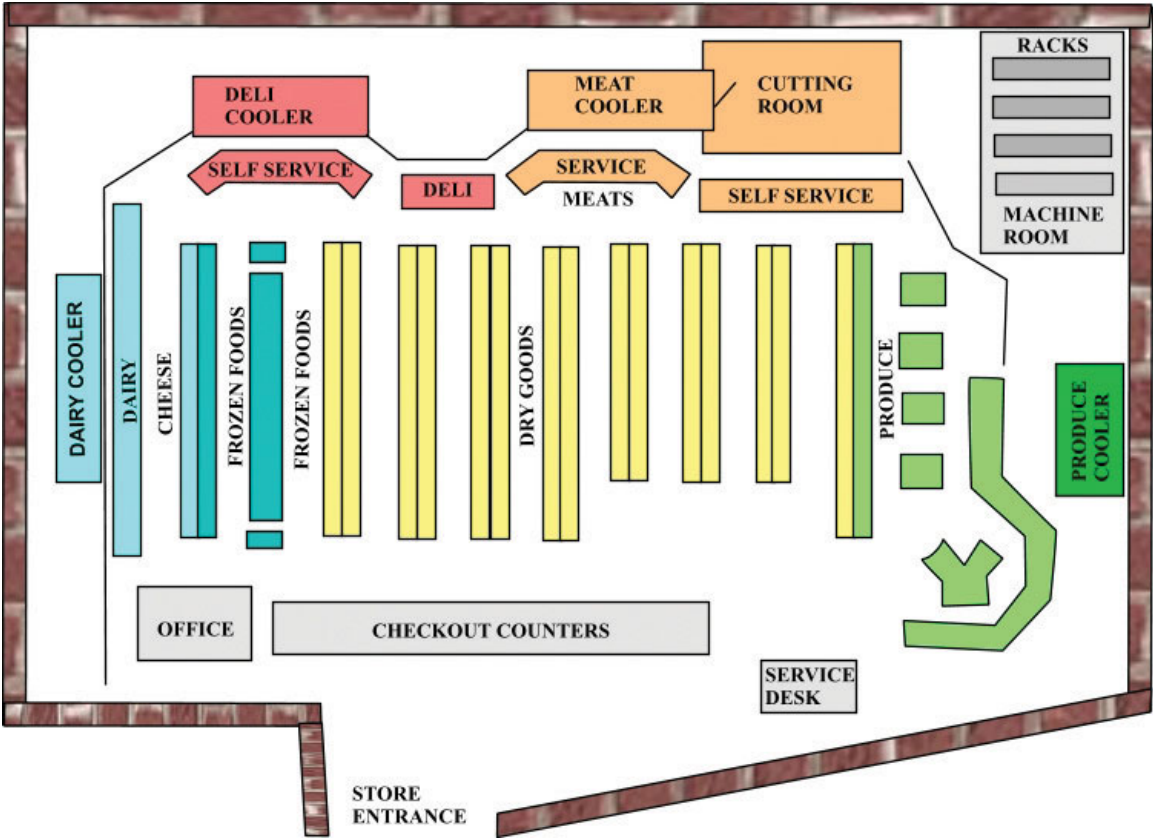

Figure 86-1 Typical supermarket layout.

Figure 86-2 Multiple DX system (multiplex).

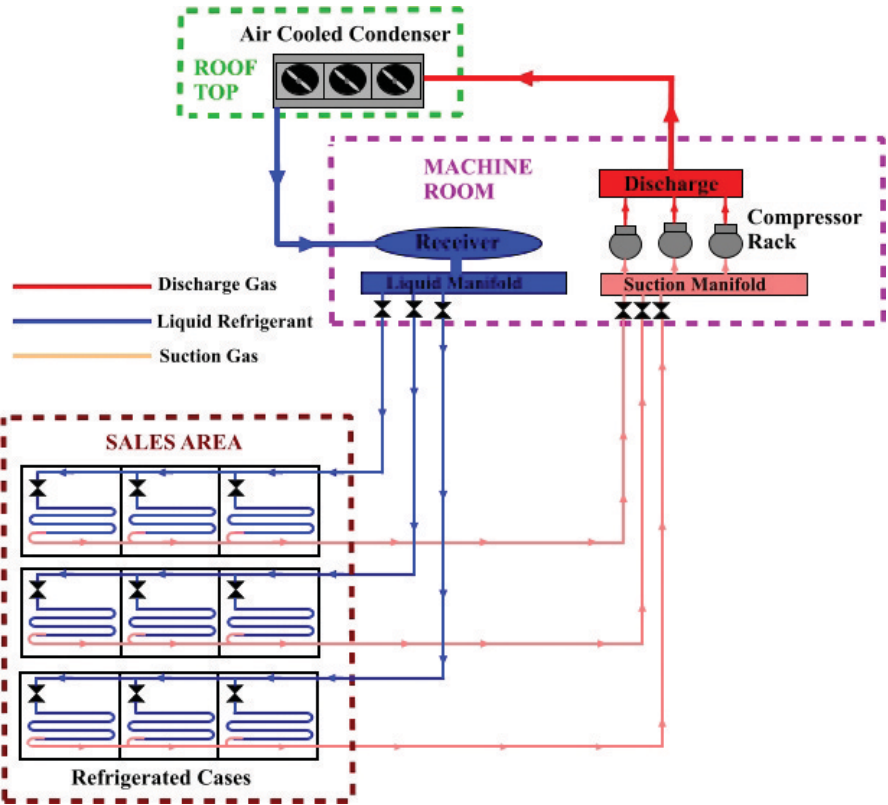

Figure 86-3 Compressor rack C operates at 15°F, and rack B can be seen directly behind it.

Figure 86-4 Rack with three scroll-type compressors.

more capacity than needed wastes considerable costly energy, and frequent cycling on and off accelerates wear and shortens the useful lifetime of motors, contactors, and other components. A rack that utilizes multiple parallel compressors is better designed to match the load under varying conditions.

As an example, three 10-horsepower (hp) compressors used in an even parallel rack will provide the four capacities of 0, 10, 20, or 30 hp. An uneven parallel rack of one 10- and two 20-hp compressors will provide more combinations that include 0, 10, 20, 30, 40, or 50 hp. Four compressor racks can provide ten different capacities or more. These types of uneven rack systems rely on microprocessor controllers and control system software provided with temperature- and pressure-sensor information for accurate and repeatable control. The increased number of capacity steps better matches the load and increases system efficiency.

Piping from a rack system to the individual cases is carried in trenches underneath the floor or overhead using hangers. Piping must be properly insulated and isolated to prevent the possibility of electrolytic action, as shown in Figure 86-5.

TECH TIP

One disadvantage of parallel systems is that a single leak can shut down a sizable number of cases. When possible, a refrigerant monitor should be used to alert the owner or service company of a refrigerant leak.

Figure 86-5 Piping arrangement of a rack system to several refrigerated cases.

Rack Components

Compressor racks will include many standard refrigeration system components depending on their type and design. Liquid-line driers are installed to remove water from the system and must be periodically replaced as a preventative maintenance item (Figure 86-6). Compressor oil is separated from the discharge gas and returned to the crankcase. An oil separator is shown in Figure 86-7, and an electronic oil level control is shown in Figure 86-8. The liquid receiver will have a level sensor (Figure 86-9). Compressor safety and cycling controls include high-pressure and low-pressure cutout switches (Figure 86-10). Subcoolers are used to lower the temperature of the liquid refrigerant leaving the machine room to reduce the amount of flash gas through the expansion valve located at the inlet of the refrigerated case evaporator coil. A subcooler using the high-temperature rack refrigerant to subcool the low-temperature rack refrigerant is shown in Figure 86-11.

Figure 86-9 (a) Compressor rack liquid receiver. (b) Level indicator for liquid receiver.

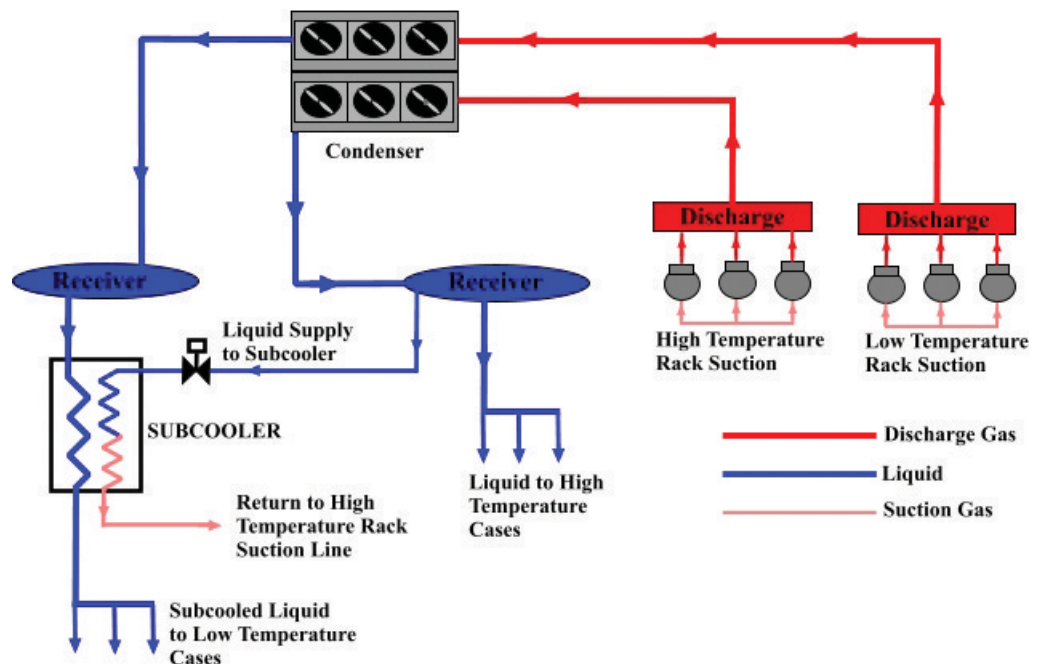

Figure 86-10 Compressor rack high-pressure and low-pressure cutout switches.

Condensers

Air-cooled condensers are very common due to their low cost and maintenance. However, the condensing temperature is directly affected by the outside ambient air temperature and will vary considerably. Higher discharge pressures use more energy, and lower discharge pressures can affect the pressure drop across the expansion valve. Therefore, some type of condenser pressure controller will be required, such as cycling fans, condenser bypass, or some combination. Evaporative condensers are more efficient and will reduce condensing temperatures, but they are more difficult to maintain.

Figure 86-11 Subcooler arrangement.

Typically the operation of the fans can be controlled to maintain a minimum high-side pressure during low outdoor temperatures. The fans can either be cycled off and on as needed or the speed of the fans can be controlled. Some designs will use a split condenser, which is a condenser split into halves and piped in parallel. At a certain outdoor temperature, the cycling of the fans may not be sufficient to maintain a minimum high-side pressure. In this design, with the use of solenoid-controlled three-way valve and a check valve, half of the condenser can be shut off from the system (Figure 86-12). This reduces the condensing area and will cause the high-side pressure to increase.

**Figure 86-12** A three-way valve used on a split condenser.

Direct Expansion Coils

The refrigerant must travel from where the compressors are located in the machine room throughout the store to the individual refrigerated cases. This results in the need for a very large amount of refrigerant, as much as 3,000 to 5,500 lbs. Because of the large quantity of refrigerant, it is not unusual for refrigerant leakage rates to be as high as 30 percent.

The case coil will have temperature and refrigerant superheat controllers. Older systems may have typical solenoid valves that open and close to control the case temperature and diaphragm-operated TEVs for superheat control. New multiplex systems will have electronic valves and controls.

Electronically Controlled Expansion Valves

Electronically controlled expansion valves can be pulse-width modulated, heat motor valves, or step motor valves. They do not rely on diaphragm operation like traditional expansion valves. A separate case controller that receives temperature, and pressure inputs from the coil will electronically control the valve.

The pulse-width modulated valve shown in Figure 86-13 is located inside the case under the meat trays (Figure 86-14). This type of valve opens and closes quickly to control refrigerant flow to the coil. Within a period of 6 seconds, a voltage signal from the controller will be transmitted to and removed from the valve coil. If there is a demand for refrigerant, the valve will remain open for almost all of the 6 seconds. If there is little demand, the valve will only stay open for a fraction of the 6-second period. This type of valve includes a tight shut-off function, which eliminates the need for an additional solenoid valve.

A step motor expansion valve will deliver more precise control and excellent repeatability. These valves are further

Figure 86-13 Pulse-width modulated expansion valve located in refrigerated meat case.

Figure 86-14 Expansion valve is located under the left side of the meat case.

explained in Unit 17, Metering Devices. Power pulses will rotate the stepper motor in either direction, which connected to the valve spindle will either open or close the valve. They can also be designed for a solenoid tight-shutoff function as well as bi-flow operation.

Case Controllers

Case control modules receive inputs from the coil sensors measuring temperatures and pressures. These electronic controllers are able to regulate all of the case functions, such as day and night thermostats, defrost, fan control, rail heat control, alarm functions, lighting, etc. They are designed to operate the case in the most efficient manner and can also provide signals to other controllers tied into a network.

Where electronically controlled valves are used, the typical case configuration is not very different from that found in a traditional refrigeration system. There will be a case temperature sensor acting as a thermostat to modulate the flow of refrigerant on or off. There will be a temperature sensor and a pressure sensor to measure the condition of the refrigerant leaving the coil for superheat control (Figure 86-15). These sensors send their information to the controller, which then regulates the valve accordingly.

Figure 86-15 Valve sensors wired to case controller.

These inputs will also be used to determine if alarm conditions have been met. Some alarm limits include the following:

- Too low a temperature
- Too high a temperature during normal operation
- Too high a temperature during cool-down after:
 - Internal or external stop
 - Defrost cycle
 - Power failure
 - Appliance cleaning

System Controllers

System controllers can be networked to the individual case controllers for monitoring all functions at one convenient location (Figure 86-16). In addition, the refrigeration rack controls and condenser controls can be networked to the system controller. System controllers can also be used for the stores HVAC systems. This allows the entire refrigeration and HVAC system to be monitored and controlled

Figure 86-16 System controllers for both the refrigeration and HVAC systems located in the machine room.

through a supervisory system. System controllers can also be tied to external communications to allow off-site monitoring or control of the systems.

Defrost

There are a number of different defrost methods that can be used, such as natural defrost, electric heat, or hot gas. There are also different ways to begin a defrost cycle. There can be manual defrost, regular interval defrost, and an automatic (adaptive) defrost. A manual defrost is initiated when the controller is set to begin a defrost sequence. An interval defrost can be programmed to begin on a regular basis, such as every 8 hours. An automatic defrost occurs when sensors indicate there is a need to begin the defrost cycle.

Adaptive defrost systems initiate the defrost system based upon measured parameters rather than a timed cycle. As an example, if the registered air flow through the coil is reduced due to ice buildup, then a defrost cycle will be initiated. The case controller does not necessarily require an actual air flow measurement. Electronically controlled expansion valves can act as mass flow meters. This can be accomplished by comparing the energy admission on the refrigerant side of the valve to the energy admission on the air side of the valve.

TECH TIP

Electronic systems are “intelligent.” Multiple inputs from a variety of sensors can be used to determine system operating conditions. Take your automobile as an example. There may be an indication of the transmission temperature, but there is no sensor that measures this directly. Other sensors that are measuring engine torque and speed are used to calculate what the expected transmission temperature should be.

A natural defrost cycle begins by shutting off the refrigerant flow and the coil is allowed to empty any remaining refrigerant. The fans remain on during the defrost cycle to help defrost the coil using air circulation. This method will take a considerable amount of time if there is substantial ice buildup. This leads to increased case temperatures during the defrost cycle.

Electric heat is faster than natural defrost and is also fairly simple, but it will consume a considerable amount of power. During the defrost cycle, the refrigerant flow is stopped and the coil is allowed to empty any remaining refrigerant, just as in the natural defrost cycle. However, at this point the fans will be shut off and the electric strip heater will turn on. When the defrost cycle is concluded, the heater will turn off and the refrigerant will begin to flow again. The fans will only start after a brief delay so that any remaining drops of water will freeze on the coil rather than being splattered throughout the case.

Hot-gas defrost is more complex but it is fast and requires less overall energy. The cycle will progress in the same manner as the electric defrost, but instead of an electric heater turning on, a hot-gas valve will open to allow high

pressure and temperature refrigerant gas to flow through the evaporator coil. The refrigerant flows backward through the coil and out through a check valve into the liquid line (Figure 86-17). Upon completion of the defrost cycle, a small drain line is used to equalize pressure between the evaporator coil and the suction line. After the refrigerant begins to flow again, the fans will start after a brief delay.

The defrost cycle will stop based on time, a temperature limit, or manually. A timed defrost cycle will last for a specific period of time such as a 10-minute defrost cycle. A temperature defrost will last until a set temperature is reached. Timed and temperature defrosts can be combined so that if the temperature limit is reached before the time limit, the defrost cycle will end. Or, conversely, the defrost cycle can be set so that if the time limit is reached before the temperature limit, the defrost cycle will end.

86.3 SECONDARY-LOOP REFRIGERATION SYSTEMS

Secondary-loop systems reduce the total amount of refrigerant charge required. In traditional multiplex DX systems, a large amount of refrigerant is contained in both the condenser and the case evaporator coils. One type of secondary loop uses chilled fluid (often a propylene glycol solution) to cool the cases rather than a primary expanding refrigerant. Another type of loop circulates glycol through the condenser located next to the compressor rack to minimize the length of refrigerant piping. This condenser secondary loop can be integrated with a heat recovery system that utilizes air-source or water-source heat pumps. These two types of secondary loops can be used separately or combined. A case coil secondary loop combined with a condenser secondary loop would have the lowest total refrigerant charge.

- Case coil DX/air-cooled condenser (largest charge)
- Case coil DX/condenser secondary loop
- Case coil secondary loop/air-cooled condenser
- Case coil secondary loop/condenser secondary loop (least charge)

Case Coil Secondary Loops

For systems that use a case coil secondary loop, the chilled fluid such as glycol does not evaporate and change phase but instead is pumped through the cooling case coil as liquid (Figure 86-18a). The glycol is cooled when it returns from the case to the evaporator, which is located close to the compressor rack, which in this configuration is often referred to as a “chiller.” The primary refrigerant is used for cooling the glycol in the chiller and is not delivered to the individual cases. This eliminates the need for long pipe runs of refrigerant as required in multiplex DX systems, which considerably reduces the amount of charge required. Long refrigerant runs of multiplex systems incur large pressure drops and result in high-suction-gas superheat. These conditions reduce the mass flow rate of the compressors, which results in loss of refrigeration capacity for multiplex systems. Even so, secondary loops also have their own drawbacks. The total energy demand for secondary-loop systems is slightly higher as compared to multiplex DX

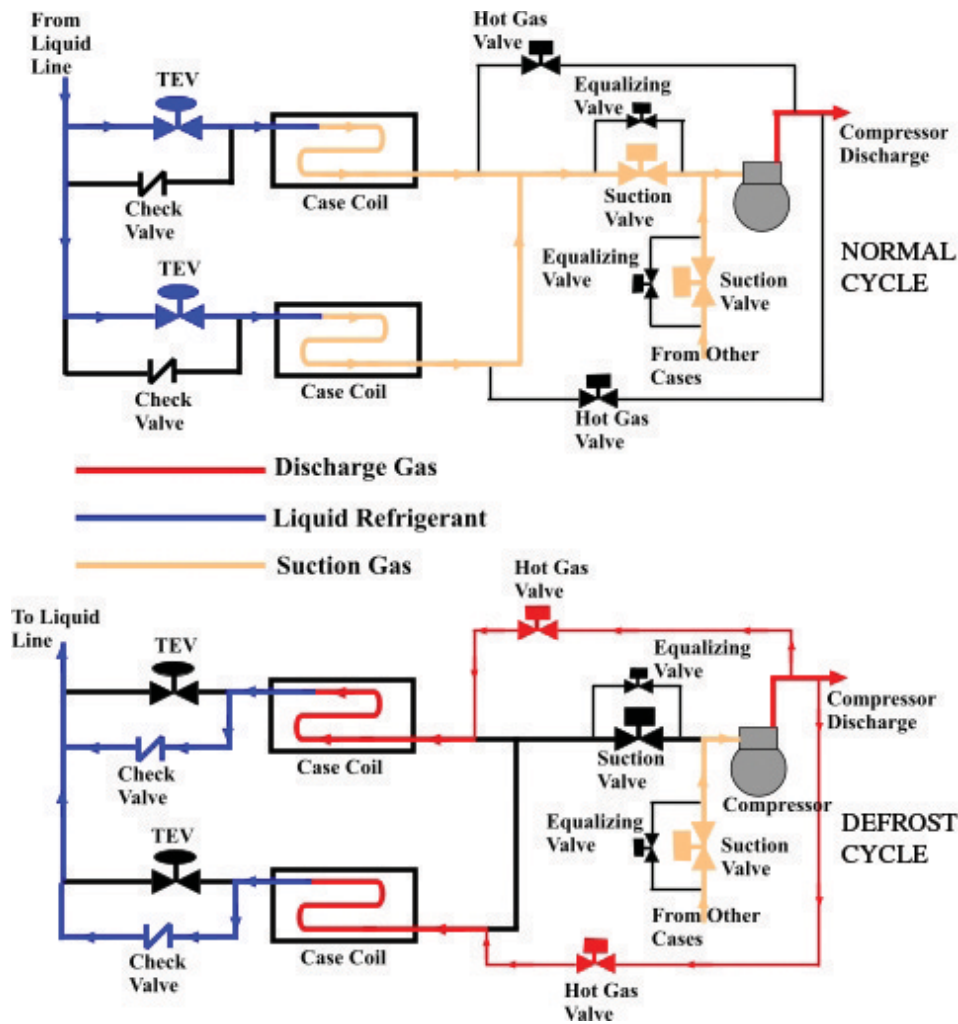

Figure 86-17 Hot-gas defrost arrangement for refrigerated case evaporator coil.

systems. This is partly due to the additional power required to pump the secondary refrigerant.

The cooling cases require coils and temperature control valves, and fluid flow is regulated to maintain the air temperature setpoint. Some secondary fluids such as propylene glycol can operate at temperatures below -20°F and are low enough in toxicity to be used in food applications. The piping used to circulate the glycol can be steel, copper, or high-density polyethylene. The glycol is dyed so that leaks can be easily detected.

Since the glycol remains a liquid, only sensible heat is transferred in the case coil, so it must enter the case at a low temperature. To keep the glycol temperature low enough for good heat transfer, the piping requires insulation. The typical glycol temperature change across the coil is 7°F to 10°F , and because of this the glycol flow rate is fairly high. This high flow rate, along with a higher viscosity of the glycol at low temperatures and almost continuous circulation, requires considerable pumping energy. A single stand-alone glycol-circulating pump must bypass excess fluid back to the suction side to avoid throttling losses at low loads. A better alternative is to incorporate multiple, parallel pumps that can be cycled on and off. This will better match the cooling load and use less en-

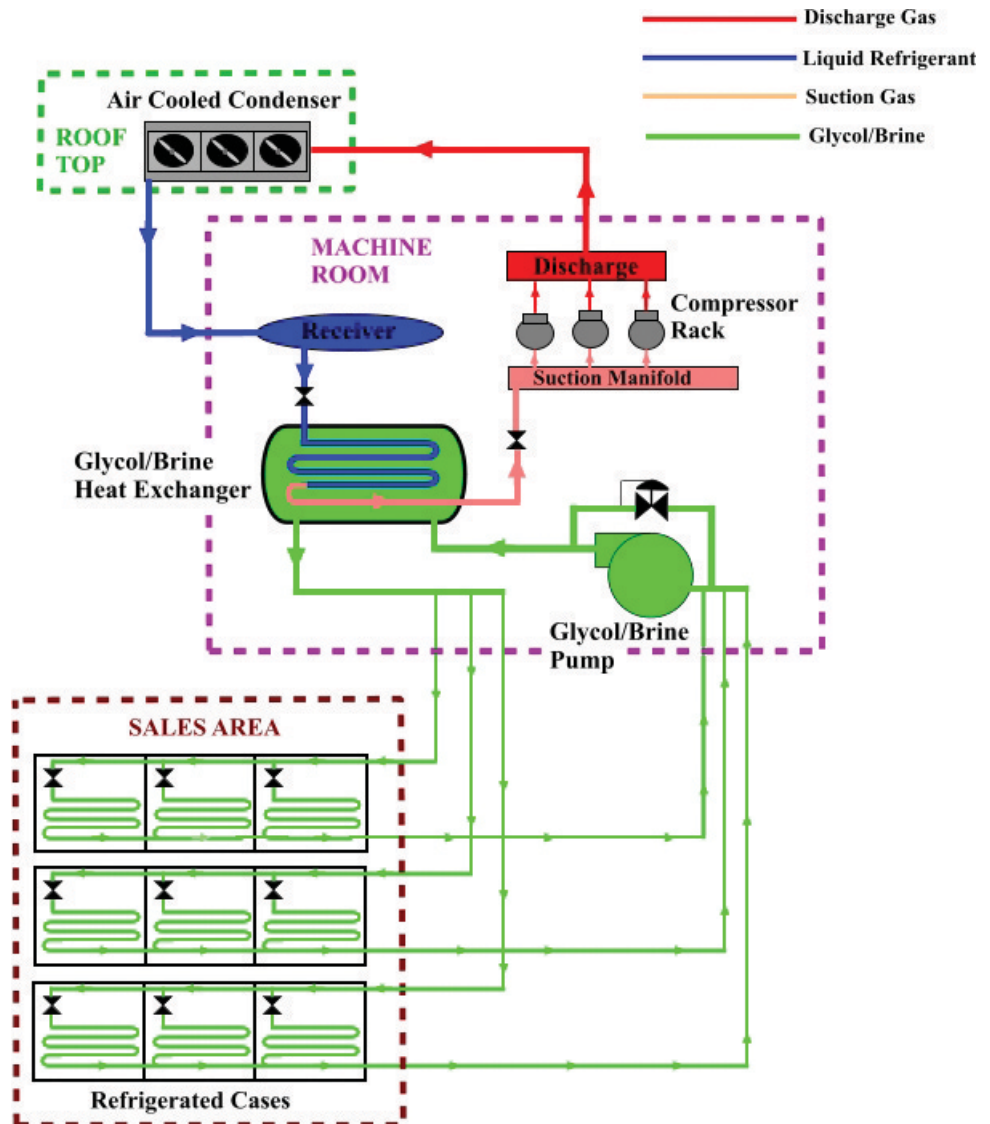

ergy. Pumps are added or subtracted based upon the pressure difference between the supply and return flow of the glycol.

There are generally at least two separate secondary loops and chillers. One for the low-temperature frozen food cases (see Figure 86-18b) and a second for the medium-temperature chilled food cases (see Figure 86-18c). However, depending on the store layout and case operating temperatures, more than two different temperature loops may be installed. This will raise the effective average evaporator temperature of the system and improve energy efficiency, although initial installation costs will be considerably higher.

Secondary-Loop Defrost

The defrost cycle for the case coil can be designed to utilize the glycol that has been heated rather than chilled. A heat exchanger located just after the receiver in the chiller liquid line will warm the glycol and also subcool the refrigerant. This is desirable because subcooling the refrigerant will increase the capacity of the system. A second heat exchanger located at the compressor discharge raises the glycol to a final temperature of approximately 65°F – 80°F .

Figure 86-18a Secondary glycol/brine loop for a refrigerated case coil.

During defrost, the warm glycol flows to the case coil through a separate pipe used exclusively for this purpose. At this time, the chilled glycol supply to the coils is shut off to allow the warm glycol to pass through the case coil. The warm glycol leaving the coil is returned to the chiller located in the machine room through the common return pipe system. The warm glycol is cooled as it melts the frost and therefore returns to the system at close to its normal temperature, adding little excess heat. This defrost method is faster than electric defrost.

Condenser-Cooling Secondary Loops

Secondary loops can also be used for heat rejection from the rack condenser, which can be located in the machine room rather than on the roof (Figure 86-19). This eliminates the long refrigerant lines required to deliver the refrigerant to rooftop air-cooled condensers. The secondary loop can be designed to utilize cooling water that passes through the machine room condenser and pumped to a cooling water

tower located on the roof. An advantage of this type of system is that the heat is rejected through both latent and sensible heat exchange in the cooling water tower, thereby increasing the efficiency. A disadvantage of this type of system is that some of the water will continually evaporate, leaving behind deposits that will need to be cleaned. In addition, this water will need to be continually replaced with makeup. Another problem is that this type of system is difficult to operate in cold climates because of the possibility of freeze-up.

Instead, a closed secondary loop can be designed so that a fluid with a lower freezing temperature, such as propylene glycol, can be used. Rather than using evaporative cooling, the glycol rejects only sensible heat to an air-cooled heat exchanger located on the roof. This can also be used in combination with a heat-reclaim coil to deliver heat back into the store during the colder winter months. Air-source, ground-source, and deep-well water-source heat pumps installed for the HVAC system can also be connected to the secondary loop for the most efficient heat reclaim.

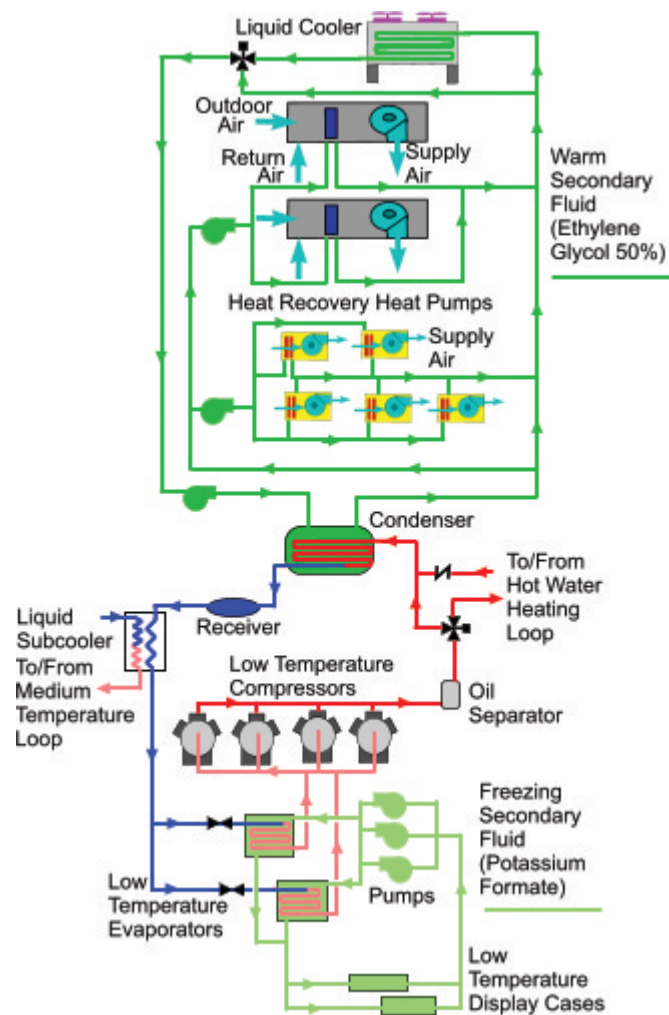

Figure 86-18b Configuration of the low-temperature secondary freezing zone.

Secondary-Loop Fluid

The loops that freeze at the lowest temperatures often use a water-based inhibited potassium formate salt (brine) solution, which can operate at temperatures down to -58°F . It is nontoxic and has a high specific heat for higher thermal efficiencies. It also has a fairly low viscosity at these reduced temperatures as compared to glycol. Because of this, it requires less energy to pump through the system. Potassium formate is compatible with many piping materials, such as aluminum, brass, bronze, stainless steel, cast iron, and copper, when it is not exposed to oxygen.

The two common glycols used for secondary loops are propylene glycol and ethylene glycol. Propylene glycol is nontoxic and therefore safer than ethylene glycol. It is rated for operating temperatures down to -20°F , with some solutions rated as low as -50°F , depending on the glycol concentration. Propylene glycol is used in the secondary loop for food display cases using medium-temperature refrigeration because it is nontoxic.

Ethylene glycol is the primary ingredient in automotive antifreeze and is toxic. It can operate at temperatures down to -40°F . Condenser-cooling secondary loops often

use ethylene glycol because it has better heat-transfer properties as compared to propylene glycol. Both types of glycol are compatible with steel, copper, or high-density polyethylene piping.

86.4 DISTRIBUTED AND SELF-CONTAINED SYSTEMS

Distributed systems utilize DX case coils similar to the multiplex DX design. However, to minimize the long runs of refrigerant lines, the compressors are distributed throughout the store near the cases being cooled (Figure 86-20). This reduces the total refrigerant charge required and the potential for refrigerant leaks. A typical store might have as many as ten to fifteen distributed systems located throughout the entire store.

Each compressor cabinet in a distributed system is similar to a multiplex rack only smaller. Multiple compressors of several sizes, usually three to five compressors for each cabinet, are piped in parallel and are cycled to match refrigeration capacity and load. Because the compressors

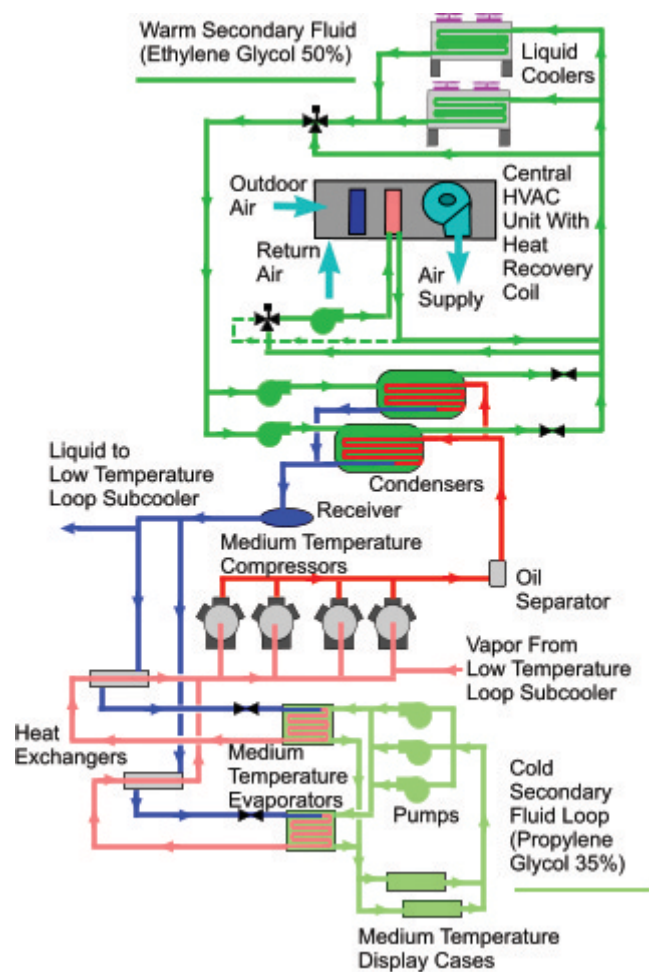

Figure 86-18c Configuration of the medium-temperature secondary fluid refrigeration zone.

Figure 86-19 Plate-type condenser located in the machinery room.

are located in the store sales area, scroll compressors that provide quiet operation and low vibration levels are most often used. A compact plate condenser is part of each package and is cooled from the closed-loop fluid cooler system similar to the condenser-cooling secondary loop described

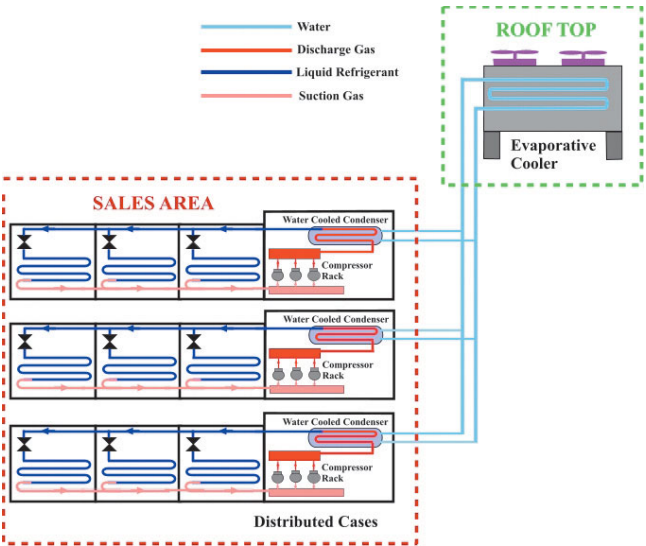

Figure 86-20 Distributed system layout.

Figure 86-21 An air-cooled condensing unit connected to a single refrigerated case.

in section 86.3. Glycol is circulated to each distributive unit plate condenser and its heat rejected to a rooftop air-cooled or ground-well heat exchanger.

Each unit includes an electronic controller that manages both compressor cycling and scheduled defrosts. Compressors are cycled to match the load requirements. A central pedestal-mounted power-distribution panel furnishes electrical power to each unit by means of a four-wire drop cord that supplies power for the compressors, fans, lights, and anti-sweat heaters.

Self-Contained Systems

Self-contained refrigeration systems are generally used in only a limited amount of display cases where the cases are inaccessible to the central refrigeration piping. An example is a refrigerated soda case located right next to the check-out lane. These units have their own air-cooled condensing units and reject heat directly into the store. An air-cooled self-contained unit used for cooling one individual case is shown in Figure 86-21.

86.5 VARIABLE-FREQUENCY DRIVES

Variable-frequency drives (VFD) to control compressor and fan motors are being used more frequently as a way to reduce energy costs. Most of these motors are three-phase AC synchronous induction motors. Their speed is directly related to the number of motor poles and the frequency of the applied current. Low frequency and therefore low motor speed at start-up reduces the high current surge encountered with conventional motors. The frequency can then also be adjusted to operate the motor at a speed that is best matched for the demand.

With conventional rack systems, parallel compressors are turned on and off by a control system, and this cycling leads to a high current inrush each time a compressor starts. This starting and stopping will also lead to wear and tear on the compressors. In comparison, rack systems that use a VFD for motor speed control can adjust the compressor capacity throughout a wide range of demand, which

limits cycling, decreases power consumption, and increases the useful life of the compressor. This same application can be applied to air-cooled condenser and cooling tower fans and also for case coil cooling fans.

86.6 OPEN DISPLAY CASES

To maintain a more appealing shopping environment, many supermarkets will display some of their refrigerated merchandise in open display cases (Figure 86-22). This is due to the belief that open display cases allow the product to be more sellable. However, current studies have shown that this may not necessarily be true, and new supermarket design is moving toward more energy-efficient closed display cases (Figure 86-23). This is partly because open display cases can absorb heat from the inside of the store, which adds to the total refrigeration load and increased energy consumption. Because of this, they have a considerable impact on the inside store temperature, which is kept relatively low. This low inside temperature may prove uncomfortable for customers and also places additional demands on the HVAC system.

Open display cases are designed and engineered to hold product at the temperature at which it enters the case (Figure 86-24a,b). They are not designed to reduce a product's temperature. They are designed to primarily handle heat leakage into the case. They also are not designed to

Figure 86-22 A typical multideck open meat case.

Figure 86-23 A closed meat case.

Figure 86-24 (a) Older-type open display case; (b) newer-type open display case; (c) air curtain temperature profile of an actual display case captured using infrared photography; (d) air flow through an open multideck case.

store product for a long period of time. Because of this, most case manufacturers recommend rotating product on a regular basis. There are several types of open display cases, which can be categorized into two general types: single deck and multideck. Since there are no doors on open cases, they rely on an air curtain to provide a barrier between the store's environment and the product (Figure 86-24c). The evaporator coil and its fans are located at the bottom of the cabinet with the fans located in front of the coil (Figure 86-24d). In a multideck case, the fans force air through the evaporator coil, up a channel at the rear and

top of the case, through a set of honeycombs located on the top front of the case, and discharge the air down in front of the case's shelving. The honeycombs are designed to even out the airflow and develop a uniform air pattern down the front or across the top of the case. In a single-deck case, the air is discharged across the top.

Single-Deck Cases

Single-deck display cases, sometimes referred to as coffin cases, are refrigerated cabinets resembling a coffin in which

Figure 86-25 A closed single-deck case.

the product is merchandised horizontally. Open single-deck cases are designed to provide an air curtain across the top of the case. These cases are less prone to problems as compared to multideck cases since the colder air, which is heavier than the warmer store air, seems to stay in the case and not spill out. Both low- and medium-temperature single-deck cases will usually have a single air curtain. An energy-efficient closed single-deck display case is shown in Figure 86-25.

Multideck Cases

Multideck cases are different than single-deck cases in that they merchandise the product in a layered vertical fashion. This allows the product to be at eye level, making it more appealing to the customer. Produce is often displayed in multideck cases. A commonly used produce case is shown in Figure 86-26. It is sometimes referred to as a vision-type case because mirrors are used to enhance the appearance of the product. Some of these cases will also have a misting system to wet down the produce as needed, as some produce products need to be kept moist. This increases the shelf life of the product and increases its appeal to the customer. A basic misting system consists of a water tube with multiple spray heads, a timer, a water filter, and a solenoid valve.

Figure 86-26 A typical produce case.

Figure 86-27 A lineup of multideck dairy cases.

Dairy products can also be displayed in multideck cases. A typical dairy case is shown in Figure 86-27. These cases normally operate at a discharge-air temperature of approximately 36°F. Single-deck or multideck cases can be used to display meat products and frozen food products. These cases normally operate at a discharge-air temperature of approximately 26°F.

Multideck Open-Case Air Curtains

The multideck open-case air curtain is directed down the front of the case opening with the discharge air on the top of the opening and the return on the bottom of the opening. As compared to single-deck cases, these are more prone to problems since it is easy for the air curtain to become disturbed. Therefore, most service problem relating to air curtains will be found on the multideck cases.

Medium-temperature multideck cases usually have a single air curtain, while low-temperature multideck cases will usually have three separate air curtains. Since low-temperature multideck cases are more prone to problems with heat leakage into the case, three air curtains are needed to provide a sufficient barrier: a primary air curtain, a secondary air curtains, and an ambient air curtain. The primary air curtain is the coldest air curtain and is closest to the product. The secondary air curtain is slightly warmer than the primary and is in front of it. The ambient air curtain is actually a blanket of store air that is directed straight down the front of the case. This air curtain is not circulated within the case.

Air Curtain Velocity

Since open cases rely on an air curtain to seal the product from the store's environment, it is important to make sure it is sufficiently maintained. Otherwise, warmer and more humid store air will migrate into the case, causing the case temperature to rise and the evaporator coil to frost up more quickly. To test an air curtain, the air discharge velocity at the supply outlet is measured. This velocity can then be compared to the manufacturer's guidelines for the case. It is important to obtain the correct velocity from the manufacturer for a particular case. As a general guideline, medium-temperature single-deck cases will have an approximate discharge

velocity of 120 to 140 feet per minute (fpm). Single-deck low-temperature cases will have a discharge velocity of approximately 200–250 fpm. Multideck medium-temperature cases will have a discharge velocity of approximately 170–400 fpm. (This depends on the application and manufacturer.) The primary air curtain of a multideck low-temperature case will have a discharge velocity of approximately 550 fpm; the secondary air curtain will have a velocity of approximately 400 fpm; and the ambient air curtain 250 fpm.

Air Curtain Troubleshooting

An air curtain can be disturbed by several factors. A technician needs to identify potential problems and correct them. A heating or air-conditioning diffuser can disturb an air curtain. If a supply diffuser is directed toward a case, it could disrupt its air curtain. Generally, velocities of over 20 fpm by the case are considered excessive.

Another way an air curtain can be disturbed is by how the product is loaded in the case. Each case is normally marked with a load-limit line. The product should not be loaded beyond this line; otherwise the air curtain will be disturbed and cause a problem.

If an air curtain is suspected of being disturbed, a technician can usually identify this in one of two methods. One method is to place a thin plastic bag in front of the case and its air curtain. (The bags used for fresh produce in a supermarket work very well.) If the plastic bag is drawn into the case, the store air will be, too; the cause will need to be identified. Another method to test the integrity of an air curtain is to smoke the case, as shown in Figure 86-28. By using a smoke candle to introduce smoke into the return-air grille, a technician can easily see if the air curtain is intact or is being disturbed. Smoke candles can be found at most local HVACR supply houses. These candles can be purchased to burn from 30 to 60 seconds. A 30-second burn is usually sufficient to test an air curtain.

Open-Case Discharge-Air Temperature

Another area of importance when troubleshooting open cases involves checking the discharge-air temperature. It is standard practice for an open case to be controlled and

Figure 86-28 Smoking a refrigerated meat case.

Figure 86-29 Temperature sensor located at the discharge-air honeycombs of an open display case.

monitored by its discharge-air temperature, shown in Figure 86-29, and *not* the interior case temperature or the return-air temperature. This is different from other types of refrigeration equipment, which may be controlled and monitored by either the return-air temperature or box temperature. Since there are major differences between the discharge-air temperature, the box temperature, and the return-air temperature, a technician should not confuse the three when servicing these cases.

The control system for open display cases can also be configured to set off an alarm if the discharge air temperature exceeds a predetermined temperature for a specific delay period. For example, an alarm temperature of 45°F with a 60-minute delay could easily be used to signal a problem with the case. The alarm can be either a local or remote alarm. A local alarm will set off some type of light or buzzer in the store to notify personnel of a problem. A remote alarm will notify someone outside the store that there is a problem, such as a facilities manager, refrigeration contractor, or alarm company.

TECH TIP

Measuring various types of temperatures is a common task for HVACR technicians. The thermometers used must be accurate for a technician to be able to properly troubleshoot a system, so technicians should occasionally test the accuracy of their thermometers.

Place a thermometer in a solution of ice and water to do this. Fill a bucket with crushed ice and add water so that $\frac{3}{4}$ of the ice is immersed in the water. It is best to have a solution that has more ice than water. Let the temperature of the solution stabilize—it should stabilize close to 32°F.

Once the temperature of the solution has stabilized, place the thermometer in the ice/water solution. Let the temperature measured on the thermometer stabilize, and observe its reading. If the thermometer measures a temperature relatively close to 32°F, then the thermometer is relatively accurate. If not, the thermometer needs to be adjusted, repaired, or discarded.

Store Humidity and Radiation Effects

Air curtains cannot totally eliminate all of the store air from migrating into a case. Small amounts of air will always migrate through the air curtains into the case. It is important to limit the store humidity level to 55 percent to keep these cases working properly. High store humidity will cause the case's evaporator to frost up more quickly, resulting in frost accumulating on the product and the system consuming more energy. A 10°F increase in the store wet-bulb temperature will increase the compressor's power usage by 25 percent.

Another source of potential problems with these cases is the introduction of radiant heat into the case. Radiant heat can be introduced into a case from its own case lighting, the store's lighting, or, depending on its location, sunlight. This can be a major source of a load on the case and should be minimized when possible.

Open-Case Defrost and Cleaning

Verifying the correct defrost times is also an important check on open cases. When possible, always check with the manufacturer for the recommended settings. General defrost norms are as follows: two to three defrosts a day for medium-temperature single-deck cases; three to four defrosts a day for medium-temperature multideck cases; one to two defrosts per day for low-temperature single-deck cases; and two to four defrosts per day for low-temperature multideck cases. Defrost times will depend greatly on the store's humidity level. The higher the store's humidity, the more defrosts the case might need.

An open case should not be installed tight to a wall, as it may cause condensation to form on the back or bottom of the case. Always allow an air space at the back of the case. When joining cases together, be sure to follow the manufacturer's guidelines and procedures. A lineup of cases that defrost together should be sealed off from any adjoining cases that defrost at a different time.

Regularly cleaning open cases is a very important maintenance task. They should be periodically shut down and cleaned out entirely to help prevent loss of product due to equipment failure. Without regular cleaning, drain lines can become clogged, causing ice to form in the drain pan and eventually rise up to stop the fans and shut the case down. Even with properly tuned refrigeration systems and proper defrost time settings, ice will develop on the ends of the evaporator coil and eventually grow large enough to possibly affect the operation of the case. Regular cleaning will prevent this from becoming a problem.

86.7 ENCLOSED DISPLAY CASES AND WALK-IN COOLERS

The refrigeration load in an open display case includes heat gains from radiation, conduction, lighting, fans, defrost, and anti-sweat heaters. And while this heat gain is significant, it accounts for only 30 percent of the total load, with the remaining 70 percent caused by infiltration. Reducing case infiltration saves energy because the refrigeration equipment accounts for approximately 50 percent of the total electrical energy consumption in a supermarket.

Figure 86-30 Closed frozen case.

This is a concern because the national focus on reducing annual energy use is beginning to affect supermarkets because they are such large energy users. Therefore, new supermarket design and retrofit have been focused on reducing energy consumption in all ways possible. Because of this, many open display cases are starting to be replaced, because it is obvious that glass-doored enclosed display cases will not be subject to such high-infiltration heat gains and therefore energy losses (Figure 86-30). Even so, there is a concern that customers find enclosed cases inconvenient and stores fear the loss of sales if open display cases are replaced. However, recent studies have shown that the enclosed display cases have little impact on product sales.

Enclosed display cases can reduce compressor rack size by as much as 15 percent. Not only that, but food safety is improved, as wide variation in product temperatures is reduced. Indoor store temperatures are warmer due to less cold air spillage, and this is more comfortable to customers. This also reduces the load on the HVAC system, which will not need to be adjusted to meet the demands of partial cooling and dehumidification by the refrigeration system.

Even with these advantages, open display cases still remain very popular. This is because even though enclosed cases reduce the total refrigeration load, they have additional energy requirements as compared to open cases. Anti-sweat heaters located in the glass doors require a substantial amount of energy. Enclosed cases also require more lighting as compared to open cases. Because of this there is very little total efficiency advantage between enclosed and open cases and not enough to warrant a retrofit change-out. However, new enclosed cases are being designed to use less energy by using "no heat" doors and LED lighting operated by motion sensors. As these improvements are standardized, the use of enclosed cases will become increasingly more cost effective.

Although enclosed cases are less prone to problems with fluctuations in the store's environment, they are still designed to operate within a desired temperature and humidity range. The store's environment should not exceed a dry-bulb temperature of 75°F and a relative humidity of 55 percent. Cases subjected to higher conditions may develop frosting and icing problems in the case, on its doors, and on the product. Even though these cases have glass doors to seal the case from the store's environment, there is still a definite air pattern set up within them just as with open display cases. The discharge temperature usually operates in a range of -10°F to 0°F (-15°F to -5°F for ice cream applications).

Figure 86-31 Walk-in cooler.

Figure 86-32 Evaporator coil for walk-in cooler.

Walk-in Coolers

There may be one or more walk-in coolers that are used to store food products until they are placed on the refrigerated cases (Figure 86-31). Walk-ins will have fan coil units located in the space (Figure 86-32). Electric defrost or hot-gas defrost is commonly used. The product is sometimes stored in the walk-in before being placed into the refrigerated display cases.

86.8 HEAT-RECLAIM SYSTEMS

Supermarket heat-reclaim systems have been in use for many years. The older series heat-reclaim systems were not very efficient, but today's systems utilizing heat pumps are designed to reduce operating costs, making them popular.

Series Heat-Reclaim Systems

Early conventional series heat-reclaim methods utilize a heat-reclaim coil located in the air handler. Heat from the refrigerant in the compressor discharge line is used to pre-heat the air for the store's HVAC system. When heating is desired, a three-way valve is used to direct the refrigerant in series through the heat-reclaim coil and then to the air-cooled condenser (Figure 86-33). The heat transferred by the refrigerant to the air handler is mainly in the form of sensible heat only. This system was originally desirable as a method to capture "free" heat that would normally be rejected to the outside through the air-cooled condenser.

The actual efficiency of series heat-reclaim systems is generally poor. This is because the refrigerant discharge

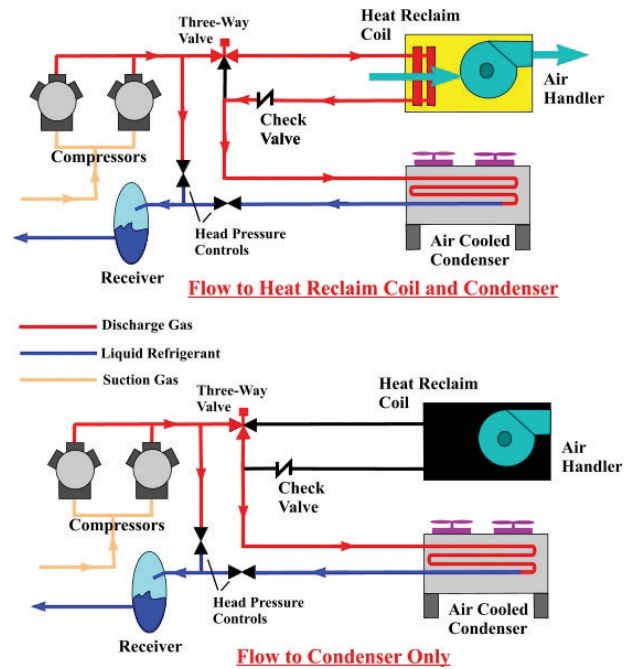

Figure 86-33 Traditional series heat-reclaim system.

temperature needs to be high enough to recover an adequate amount of sensible heat. The system relies on head pressure control valves (holdback valves) to maintain a high enough condensing temperature sufficient for heat recovery. If the refrigerant condensing temperature is too low, then the compressor's compression ratio decreases, which results in lower mass flow rates and less total heat available. A major disadvantage is that most often the electrical energy consumed by the compressors required by this floating head pressure control offsets the gains made by heat recovery. In addition, this type of system requires long refrigerant line lengths to and from the air handler. For these reasons, series heat-reclaim systems are seldom used today.

Parallel Heat-Reclaim Systems

A parallel heat-reclaim system recovers both the sensible and latent heat from the refrigerant. As compared to a series heat-reclaim system that only transfers sensible heat, the refrigerant is condensed in a parallel heat reclaim system. The reclaim coil is not in series but rather in parallel with the air-cooled condenser (Figure 86-34). This design allows for a number of different options, such as locating the heat-reclaim coil in the air handler. A disadvantage to this location is the heat rejected from the reclaim coil needs to satisfy both the compressor head pressure requirements and the air-handler demands. This requires properly designed coil sizing and is not easily controlled like a typical HVAC system. As an example, the reclaim coil could reject more heat than the HVAC system requires, which would raise the building temperature to an undesirable level.

An alternative method is to include a secondary-loop heat exchanger to condense the refrigerant. After absorbing heat from the condensing refrigerant, the secondary fluid is pumped to a sensible heat-reclaim coil located in the air handler (Figure 86-35). A disadvantage to this system is

Figure 86-34 Parallel heat-reclaim system.

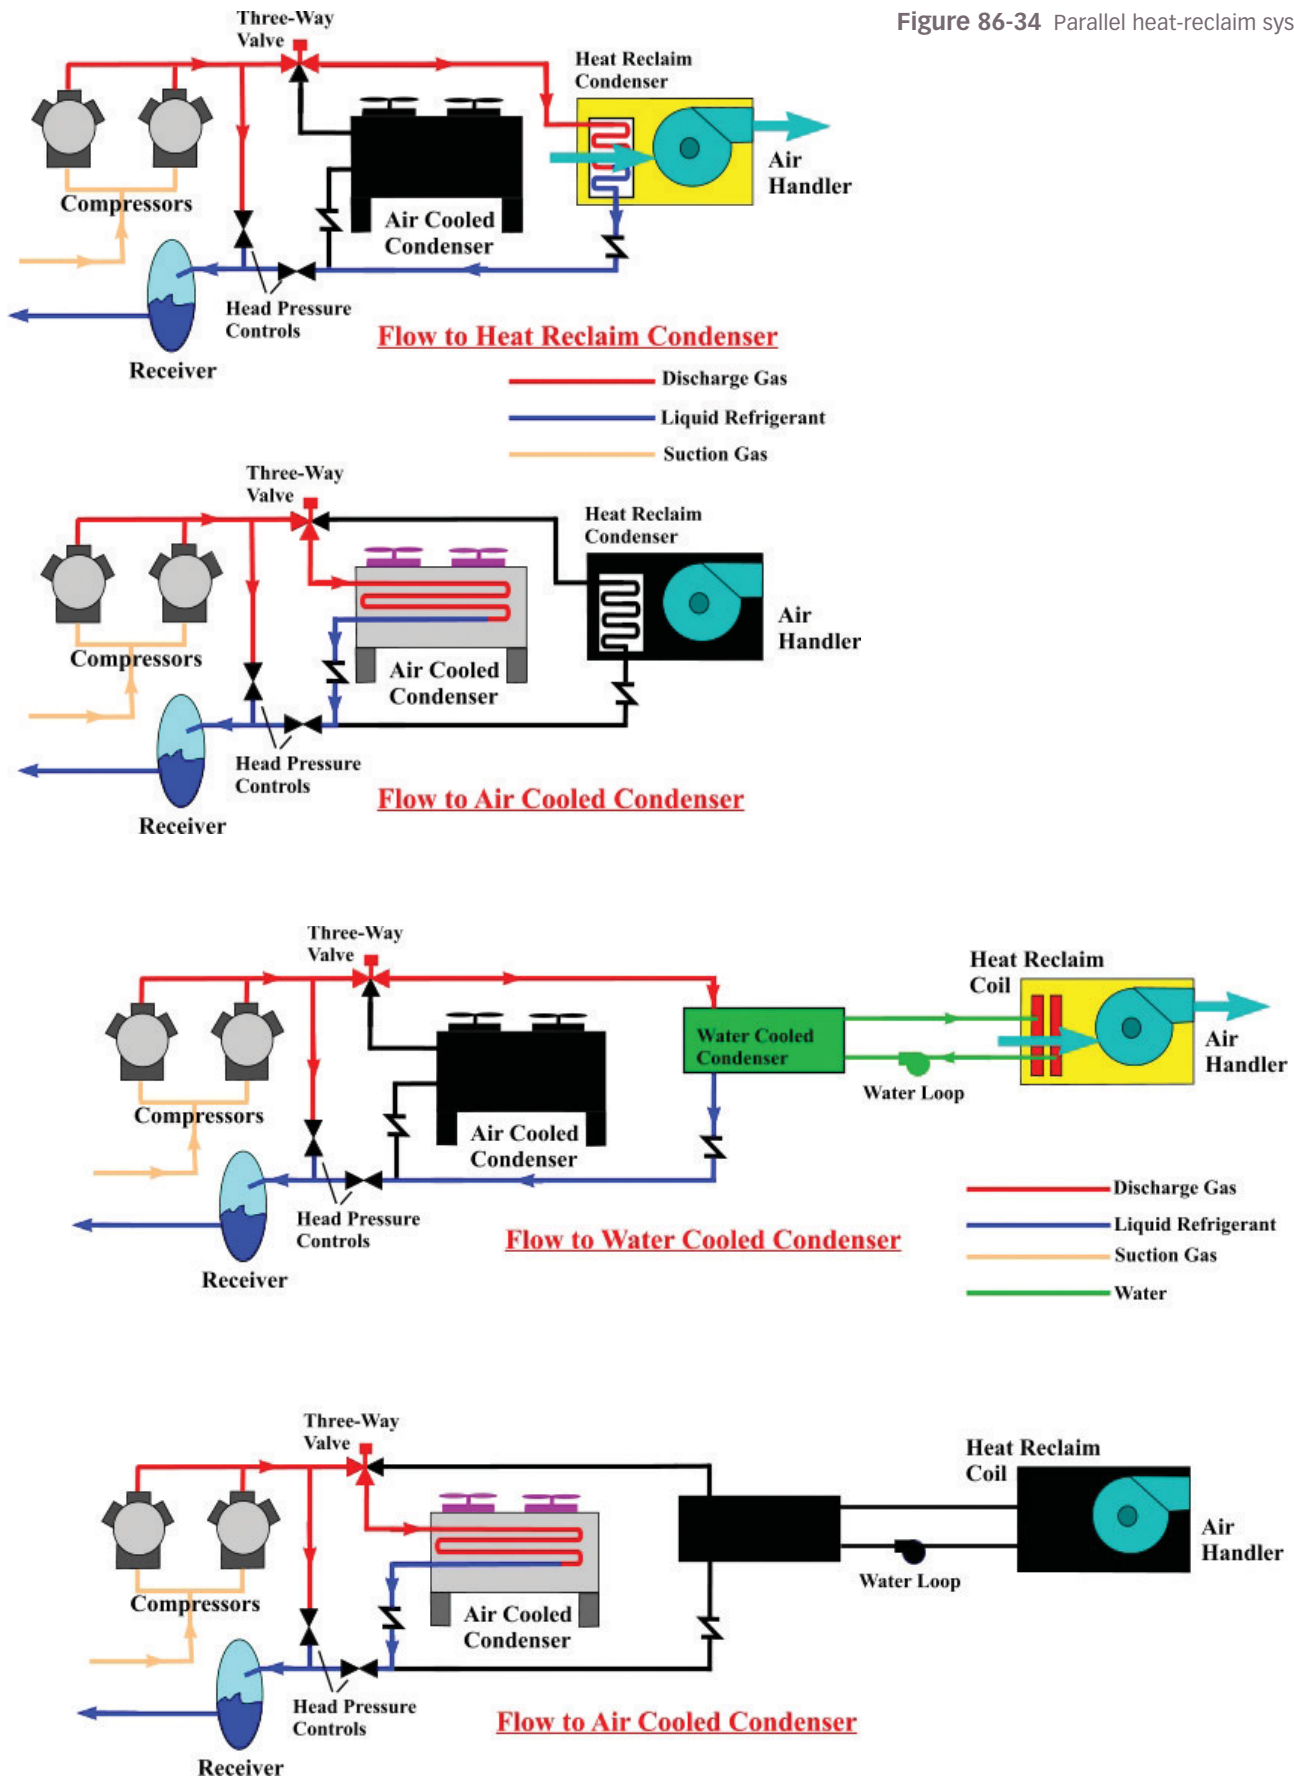

Figure 86-35 Secondary-loop heat-reclaim system.

Figure 86-36 Glycol piping.

that although both sensible and latent heat are recovered from the refrigerant, only sensible heat is transferred in the air handler. Also, additional pumps for the secondary fluid will increase electrical energy consumption.

Hydronic Heat-Reclaim Systems with Heat Pumps

Current refrigeration systems are being designed to reduce energy costs and minimize the total refrigerant charge. Hydronic heat-reclaim systems that incorporate water-source heat pumps are becoming increasingly popular. The refrigeration system uses a condenser-cooling secondary loop, and in this way the refrigerant condenser can be located next to the compressor rack in the machine room. The secondary fluid, typically ethylene glycol (Figure 86-36),

is pumped to air-cooled heat exchangers located on the roof (Figure 86-37). This same loop can incorporate water-source heat pumps that can be used for heating during the winter months (Figure 86-38). With outside air temperatures below freezing, air-source heat pumps will have a very low COP (coefficient of performance) and therefore poor efficiency. In comparison, the water-source heat pumps that recover the rejected heat from the refrigeration system will operate at a much higher COP.

To gain further efficiency, geothermal heat pumps are used for the secondary loop. Geothermal heat pumps will cool the store in the summer while the rooftop air-cooled heat exchangers reject heat from the refrigeration system. During the winter months when heat is required, the heat pumps will be used in the loop for heat reclaim. This type of system requires extensive secondary loop piping and pumps along with change-over valves (Figure 86-39). However, the initial cost for installation should be paid for over time through reduced energy costs, and this type of design will better meet new “green” building code requirements.

86.9 NATURAL REFRIGERANTS

CFC and HCFC refrigerants are being replaced by HFC refrigerants that are safer for the environment because they have a lower ozone-depletion potential. However, many of these new environmentally acceptable refrigerants have been found to increase energy consumption and therefore actually contribute to the global warming potential (GWP)

(a)

(b)

(c)

Figure 86-37 (a) Directional control valves for heat-reclaim loop; (b,c) rooftop heat exchangers.

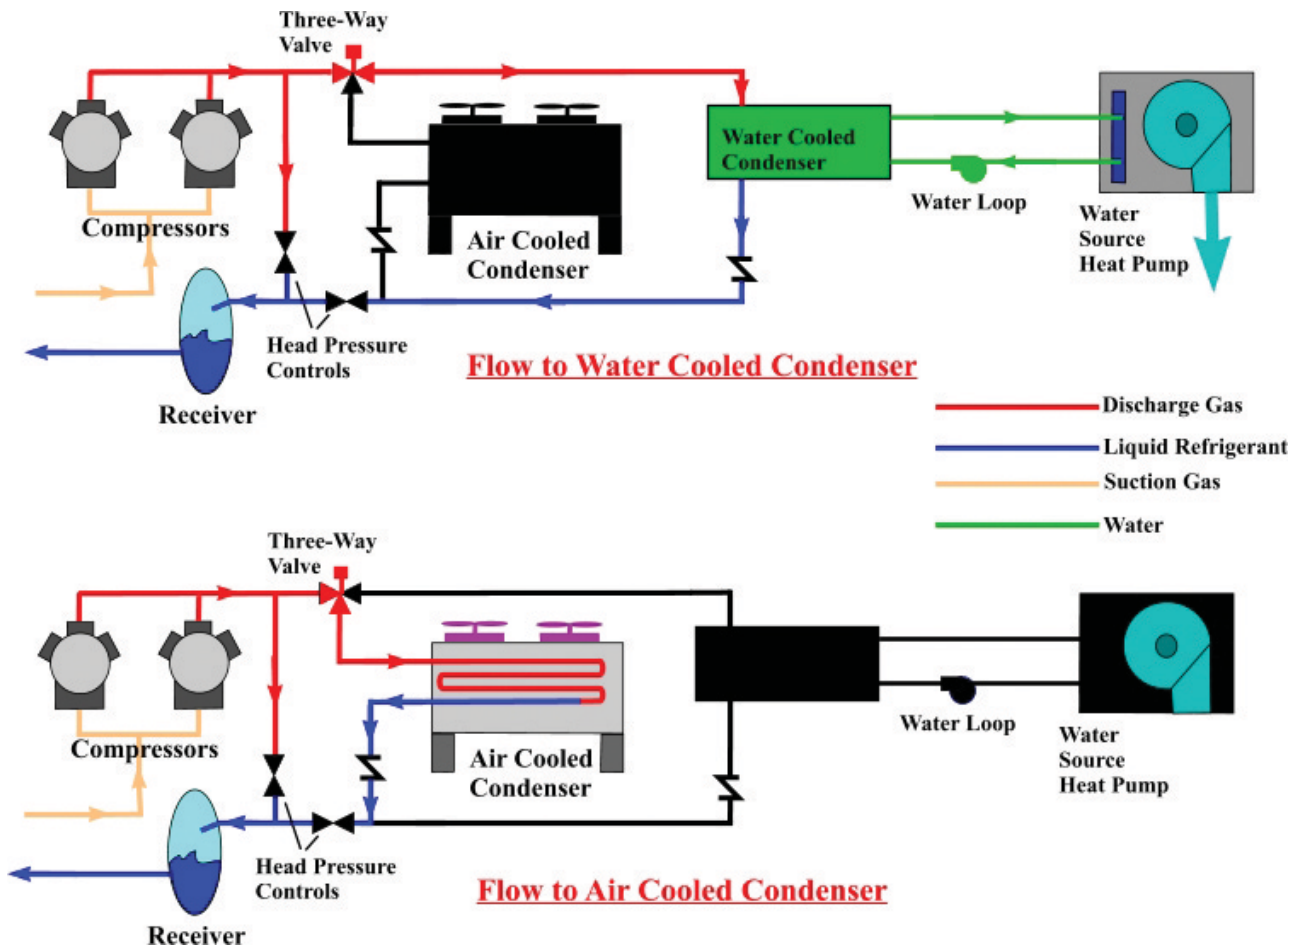

Figure 86-38 Secondary heat-reclaim system with heat pumps.

(Table 86-1). The current “green” building climate is moving toward carbon neutrality and a reduction in worldwide greenhouse emissions. Current alternative refrigerants for commercial use in large supermarkets include ammonia, CO_2 , and hydrofluoro olefins (HFO). HFOs are newly developed types of refrigerant that have a low global-warming potential (GWP).

Carbon Dioxide (CO_2) Systems

Ammonia is both toxic and flammable, and HFOs are still in the early stages of development. This has led new supermarket

R-744 (CO ₂)	0	1
HFO-1234yf	0	4

design to consider the use of CO₂ as a refrigerant. CO₂ has a low GWP, is nontoxic (within a ventilated space), nonflammable, and doesn't deplete the ozone.

CO₂ has a very high volumetric cooling capacity. It can absorb 5 or 6 times as much heat as HFCs at medium temperatures. However, CO₂ systems operate at considerably higher pressures. At room temperature, the pressure of CO₂ is approximately 913 psi. CO₂ can operate in the subcritical, transcritical, and supercritical phase. In the supercritical range at temperatures above 88°F, the vapor and liquid CO₂ are identical, and vapor CO₂ cannot condense into a liquid. Supercritical systems operate best in the 1,600 to 2,500 psi range. Systems are designed as non-cascade and cascade.

Subcritical, Supercritical, and Transcritical Systems

Subcritical, supercritical, and transcritical all describe a refrigeration system's operating pressures and temperatures

relative to the critical point of the refrigerant in the system. The critical point is the highest pressure and temperature where the refrigerant can still condense. At and above the critical point there is no distinction between gas and liquid, so no condensation or evaporation can take place. The very top of the hump in a refrigerant enthalpy diagram is the critical point. A normal refrigeration system is a subcritical system because all the system components operate at pressures and temperatures below the critical point. Subcritical systems use an evaporator to absorb heat and a condenser to reject heat. In a supercritical system, all the components operate at pressures and temperatures above the critical point. A supercritical system operates on gas compression and expansion with no change of state. All heat transfer occurs by the gas changing temperature. A transcritical system operates both above and below the critical point. Heat is absorbed in an evaporator where liquid evaporates to a gas, but heat rejection takes place above the critical point, so there is no condensation. The refrigerant does not condense back to a liquid until after the pressure is reduced.

Non-Cascade CO₂ Systems

Non-cascade CO₂ systems use a typical refrigeration cycle loop with compressor, condenser, flow control, and evaporator. A non-cascade system can be DX or transcritical. However, DX systems are not commonly used because the refrigerant is in the subcritical phase and at high pressure at normal room temperatures. Because of this, an air-cooled condenser would require very high operating pressures and therefore not be practical.

A transcritical system can operate in both the subcritical and supercritical ranges. In temperatures above 88°F, the CO₂ would be supercritical and the condenser would become a gas cooler. At temperatures below this, the system would operate as a DX subcritical system. This type of system is much more efficient when operating in the subcritical range. Because of this, the system has poor operation and efficiency in warm climates.

Cascade Systems

A cascade CO₂ system uses a secondary loop with a different refrigerant (Figure 86-40). In a subcritical DX cascade system, both loops use compressors to circulate the refrigerants. HFC refrigerant is circulated to the medium-temperature refrigerated cases and also to a heat exchanger for cooling the CO₂ (Figure 86-41). This lower-temperature cooling with the HFC allows the CO₂ to remain in the subcritical range. The CO₂ is used for cooling the low-temperature refrigerated cases. This type of system reduces the total refrigerant charge and maintains operating pressures fairly low, at approximately 450 psi.

A cascade secondary loop with liquid recirculation uses both pumps and compressors to circulate the refrigerant. HFC refrigerant is circulated by a compressor only for cooling the CO₂. This CO₂ heat exchanger is a flooded coil that has both liquid and vapor CO₂ leaving (Figure 86-42). The vapor CO₂ is delivered by compressors for cooling the low-temperature refrigerated cases. The liquid CO₂ is pumped

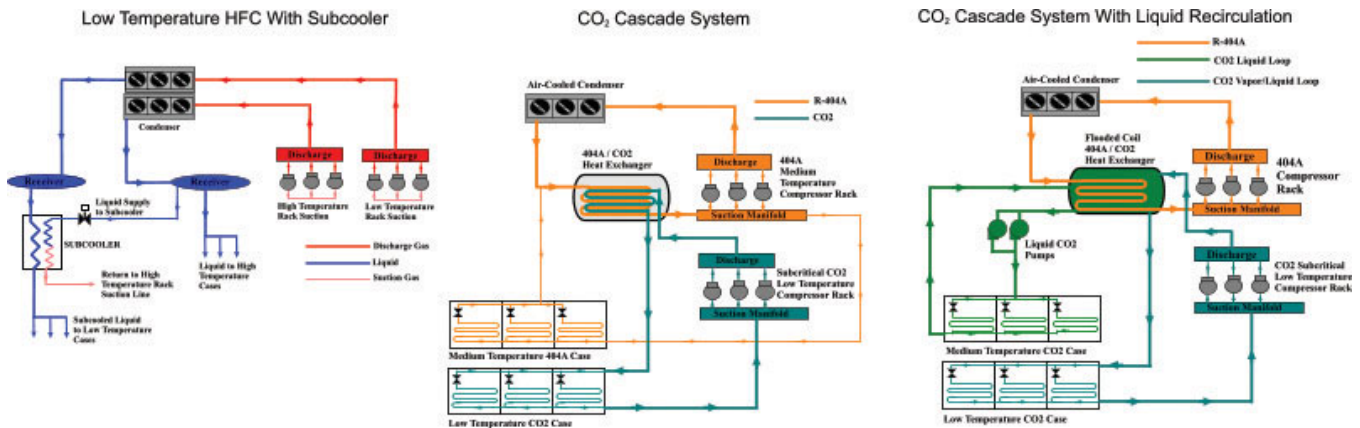

Figure 86-40 Three different types of low-temperature systems.

to the medium-temperature refrigerated cases. Similar to a cascade DX system, this reduces the total refrigerant charge and maintains operating pressures fairly low, at approximately 450 psi.

Future of CO₂

Over a dozen CO₂-based supermarket installations have been completed successfully in the United States. Over five hundred supermarkets are currently using CO₂ in Europe. Since this technology is relatively new, there are

concerns about having properly trained people to operate and service these systems. Just a small increase in temperature results in a significant rise in pressure. Systems need to be kept below 88°F at all times in the event of a power outage. Systems must be designed to vent the CO₂ directly outside to prevent personal injury in occupied spaces. However, even with these operational concerns, if the trend continues toward reducing high GWPs and no significant developments are made in developing hydrofluoro olefins, then more CO₂ systems will continue to be installed.

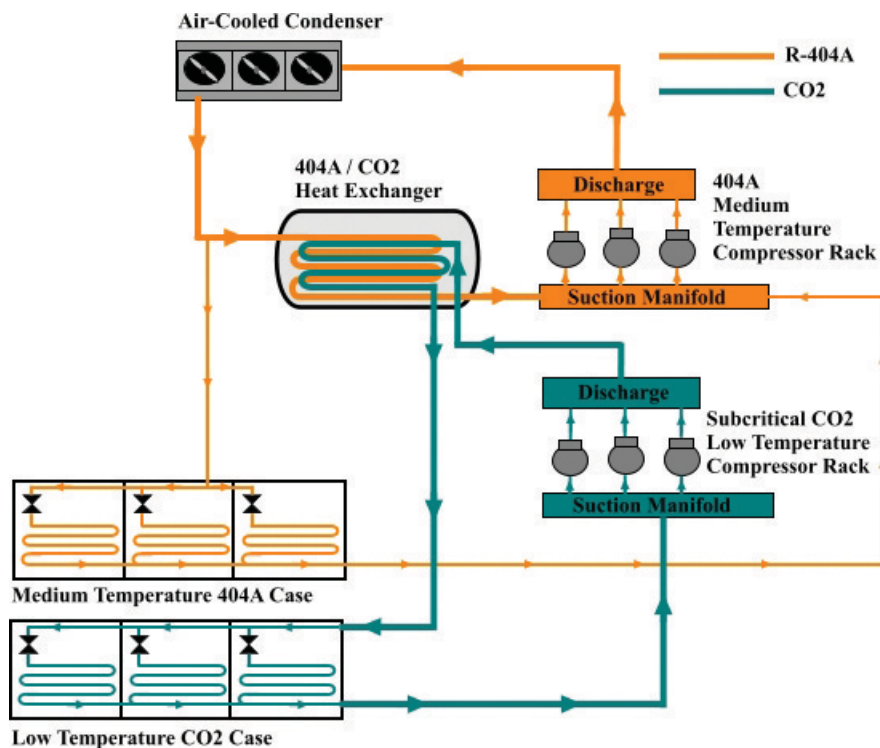

Figure 86-41 CO₂ cascade system.

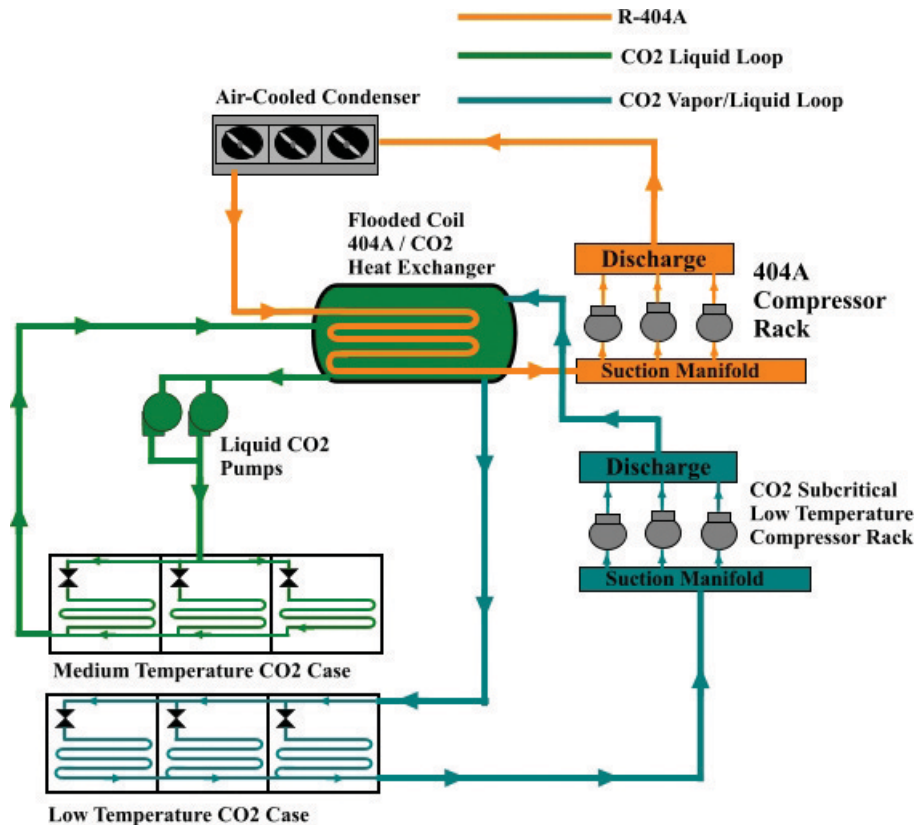

Figure 86-42 CO₂ cascade system with liquid recirculation.

UNIT 86—SUMMARY

The impact that supermarkets have on the total equivalent warming impact has been considered to be significant. Because of this, supermarket design is focusing on becoming more energy efficient. New systems have considerably lower total refrigerant charges. Secondary-loop systems are becoming more popular, and in some instances natural refrigerants such as CO₂ are replacing HFCs. Electronic control systems for compressor racks and refrigerated cases provide for more accurate metering and delivery of the refrigerant and are now common. Open cases are being replaced by closed cases to reduce air infiltration and to lower the load on the store's HVAC system. Heat-reclaim systems are being designed to utilize secondary loops in combination with geothermal heat pumps. As "green" building standards develop and new refrigerants such as hydrofluoro olefins are developed, supermarket design will continue to change.

WORK ORDERS

Service Ticket 8601

Customer Complaint: Ice on Evaporator Coils

Equipment Type: Walk-in Freezer

A technician is called out to service a walk-in freezer with an air-cooled condenser, R-404A refrigerant, and an external equalized TEV operating at a 30°F case temperature.

When the technician arrives on the job, the evaporator has an excessive amount of ice on its coils, and the compressor, condenser, and evaporator fans are running. The system incorporates electric defrost heaters and a time-temperature defrost arrangement with three defrost periods per day and a failsafe time of 35 minutes. The system also uses a standard temperature controller to control case temperature. The technician decides to initiate a defrost cycle and then observes the following conditions:

- Compressor and evaporator fans shut down.
- Electric heaters are energized.
- Ice starts to melt off the coils of the evaporator.
- The system stays in defrost for 35 minutes and then the compressor cycles back on with the evaporator fan coming on after a slight delay.

A second defrost is initiated and the following conditions are observed:

- Compressor and evaporator fans shut down.
- Electric heaters are energized.
- The remaining ice melts off the coils of the evaporator.
- The system stays in defrost for 30 minutes and then the compressor cycles back on with the evaporator fan coming on after a normal delay.

After running for approximately 45 minutes after the second defrost, the following conditions are observed:

- The operation of the time clock is observed and the time advances normally.
- The case temperature is down to 10°F.

Based on these observations, the technician determines that the system is operating normally. After speaking with some employees working in the kitchen, it is discovered that the door was accidentally left slightly open for several hours, which most likely caused the elevated case temperature and the excessive ice on the evaporator.

Service Ticket 8602

Customer Complaint: Ice on Evaporator Coils

Equipment Type: Walk-in Freezer

A technician is called out to service a walk-in freezer using R-404A refrigerant, an air-cooled condenser, TEV metering device, and a time-initiated temperature-terminated electric defrost strategy and operating at a case temperature of 28°F and climbing.

When the technician arrives on the job, the compressor, condenser, and evaporator fans are running, and the evaporator is completely covered in ice. After further investigation, the technician observes the following conditions:

- The condenser coil is clean.
- The ambient temperature is 78°F.
- The operating suction pressure is 20 psig.
- The operating discharge pressure is 229 psig.
- The resistances of the defrost heaters are measured, and each heater has a measurable resistance.
- The defrost time clock is observed for 30 minutes, and it seems to advance normally.
- A manual defrost is initiated, and the defrost time clock immediately jumps back into the refrigeration mode.

The technician then decides to replace the termination temperature switch.

UNIT 86—REVIEW QUESTIONS

1. What is the most common type of system used in “traditional” supermarkets?
2. How many compressors are typically found on a compressor rack?
3. An uneven parallel rack of one 10- and two 20-hp compressors will provide for what horsepower combinations?
4. What type of pressure control can be used for rooftop air-cooled condensers?
5. How does a pulse-width modulated expansion valve operate?
6. What types of defrost methods can be used for refrigerated case coils?
7. Explain how an adaptive defrost cycle operates.
8. What is the advantage of a case coil secondary-loop system?
9. What types of fluids are used for secondary-loop systems?
10. How is a distributed system arranged in a supermarket?
11. What is the advantage to variable-frequency drive motors?
12. Secondary-loop fluid potassium formate is compatible with which piping materials?
13. Do enclosed display cases use more or less energy than open cases?
14. How does a series heat-reclaim system operate?
15. What is the disadvantage of a parallel heat-reclaim system that has the reclaim coil located in the air handler?
16. How do open display cases maintain the temperature within the case without any doors?
17. The temperature is monitored in an open display case at what location?
18. How many air curtains are used in a multideck open display freezer?
19. What are the advantages of CO₂ as a refrigerant?
20. What are the disadvantages of CO₂ as a refrigerant?

UNIT 87

Ice Machines

OBJECTIVES

After completing this unit, you will be able to:

1. estimate the size of the ice machine required for a particular application.
2. explain the differences between cubes, crushed ice, flake ice, shaved ice, and block ice and what applications are best suited for these ice types.
3. determine if an ice machine needs to be cleaned.
4. describe the sequence of the freeze and harvest cycles of a cube ice machine.
5. describe the operation of a flake ice machine.
6. troubleshoot cube and flake ice machines.

87.1 INTRODUCTION

Ice has always been a valuable commodity. Before the advent and commercialization of mechanical refrigeration systems, ice was harvested from frozen lakes and rivers and then cut into large blocks with hand saws (Figure 87-1). Besides being stored and used locally, some of this ice was packed in sawdust for insulation and transported by sailing ships to places such as the islands of the Caribbean. Later, mechanical refrigeration systems allowed ice to be made year round, making it available for more people. Much of this ice was produced in large industrial ice-making facilities as large blocks. These large blocks were sawed into smaller blocks and cubes. The ice shavings left behind from the electric saws were collected and used in stores to keep vegetables and seafood displays cold. This is similar to the flake ice that is made specifically for such purposes today.

Industrial ice-making facilities still provide for much of the bagged ice that can be purchased in supermarkets and convenience stores. However, most commercial institutions such as restaurants and cafeterias rely on the operation of

packaged ice-making machines. These commercial ice makers come in many different sizes and are available for a wide range of applications.

Even though there are many different types of ice makers, they all have the same major refrigeration components, which include a compressor, condenser, metering device, and an evaporator (Figure 87-2). This is why it is important to have a good understanding of the basic refrigeration cycle before working on commercial ice makers.

TECH TIP

Most ice machines work on the principle of the basic mechanical refrigeration cycle. The unit will have a compressor, condenser, metering device, and evaporator. Troubleshooting these units requires a good understanding of refrigeration systems. Although there are many different types of ice machines, most manufacturers provide detailed operating and troubleshooting guidelines that are unit specific.

Figure 87-1 Ice harvesting in 1940. The sawed ice blocks from the river are being channeled to the conveyor and into the icehouse. (Collections of the Bangor Museum and History Center)

87.2 COMMERCIAL ICE MACHINE APPLICATIONS

Commercial ice machines are often used for food service applications, such as restaurants, institutional kitchens, cafeterias, and correctional foodservice. They can also be found in such places as hotels, hospitals, theme parks, resorts, casinos, and cruise ships. Some commercial ice machines can be compact for small-volume ice production. These are used when there are limited ice needs, and they do not take up much space. They can be found in places such as small kitchens, hotel hallways, and office lunchrooms. Larger machines are required when a lot of ice is needed on a fairly continuous basis (Figure 87-3). There are some machines that also automatically bag the ice, which adds to the mechanical complexity of the unit.

Production of ice will vary, with small ice machines making 50 lb of ice per day or less and large machines making

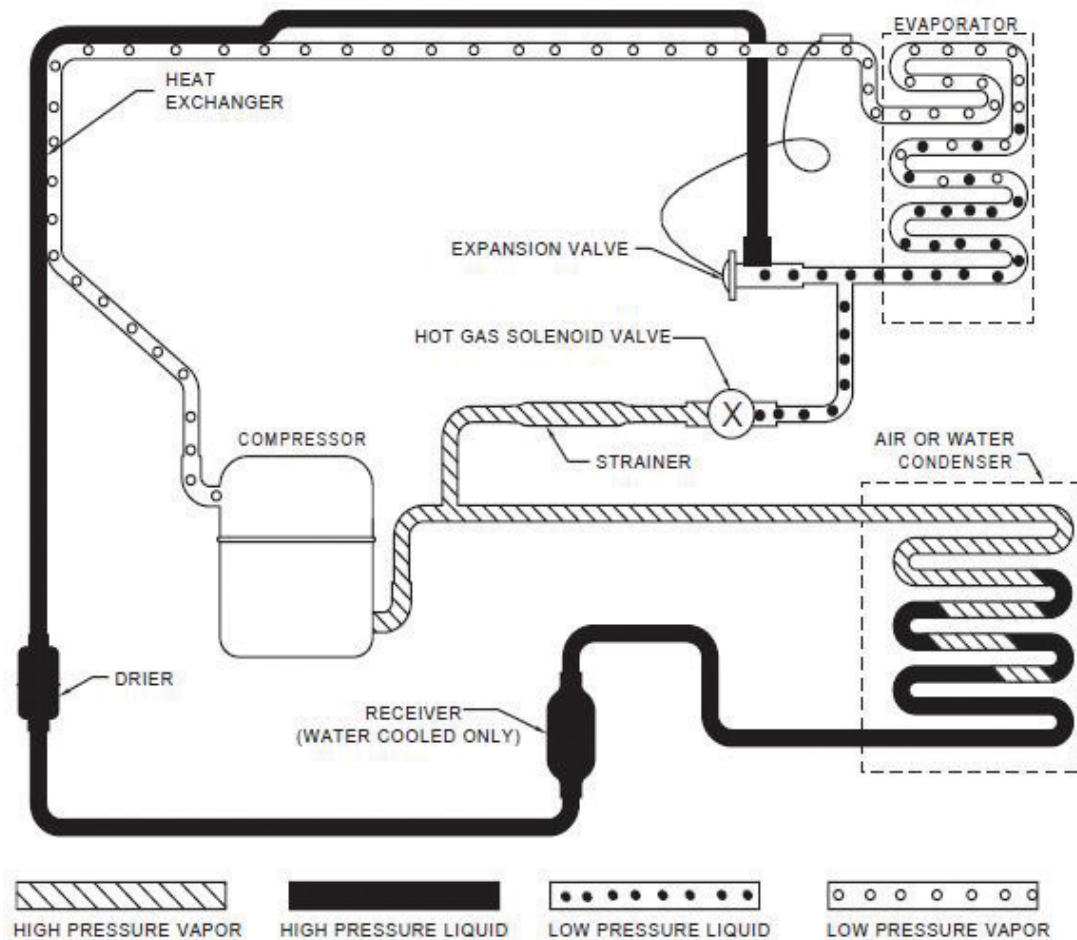

Sequence of Operation**SELF-CONTAINED AIR OR WATER -COOLED MODELS**

Figure 87-2 Mechanical refrigeration cycle for an ice machine. (Courtesy of Manitowoc)

Figure 87-3 Filling buckets with ice from an industrial ice machine. (Edward J. Westmacott/Alamy)

over 3,000 lb per day. The total amount of ice required is dependent on the application. An example of estimated ice usage based on application is provided in Table 87-1.

Table 87-1 Estimated Ice Usage

Application	Ice Type	Daily Approximation
Restaurant	Cube	3 lb per person
Cafeteria	Cube	3 lb per seat
Cafeteria	Crushed	6 lb per seat
Hotel room service	Cube	5 lb per person
Hotel food service	Cube	1.5 lb per person
Hospital	Cube	5 lb per bed
Hospital	Crushed	10 lb per bed
Salad bar	Crushed	30 lb per cubic foot
12-oz drinking cup	Cube	6 oz of ice

TECH TIP

Some small soda fountains have self-contained ice makers, while others must be loaded with ice from a large centrally located ice machine that supplies the entire cafeteria. The advantage to a unit that must be loaded with ice is that it can be quickly replenished if it becomes empty. If the centrally located unit is sized properly, then it should not normally run out of ice.

87.3 ICE TYPES

Very often we think of ice as always being cubed. However, there are many other different types of ice, such as crushed, shaved, flake, and block. Each type is made differently and has specific uses for which it is best suited.

Cubes

Ice cubes are popular for drinks because they melt slowly and cause less dilution. A full-size square cube can be as large as $1\frac{1}{4} \times 1\frac{1}{4} \times 1\frac{1}{4}$ in. This size is typically used for bagged ice, bar drinks, room service, and airlines. A dice-size cube is $\frac{7}{8} \times \frac{7}{8} \times \frac{7}{8}$ in. There would be about forty-eight dice size cubes in 1 lb of ice. A half-cube size would be about $1\frac{1}{4} \times 1\frac{1}{4} \times \frac{5}{8}$ in. These are a good size for fast food establishments and restaurants. The size of a quarter cube would be about $1\frac{1}{4} \times \frac{5}{8} \times \frac{5}{8}$ in. These are good for beverage service and are a very versatile and popular size.

TECH TIP

In 1914, Fred Wolf invented a refrigerating machine called the DOMELRE (Domestic Electric Refrigerator), which had a simple ice cube tray. The first flexible stainless steel, all-metal ice cube tray was created by Guy L. Tinkham and sold for 50 cents in 1933. The idea for the first rubber ice cube tray was thought of by Lloyd Groff Copeman in 1928. Sales from this invention earned him approximately \$500,000, which is equivalent to about \$10 million today.

Crushed Ice

Crushed ice is often used in cold drinks and is easy to chew. However, it melts faster than cubes and adds more water to the beverage. It is generally crushed from cubes, and this can be done by hand but is very time-consuming. It is known as “cracked” ice when left in larger fragments. Crushed ice has a finer texture and may need to be hand scooped rather than dispensed by a machine. This is why many machines incorporate a built-in ice crusher to allow for a choice between cube ice and crushed ice (Figure 87-4). The crusher does not add to the complexity of the refrigeration components but does add a mechanical feature that will require maintenance.

Figure 87-4 Ice crusher located in the ice chute to make crushed ice from cubes. (Courtesy of KOLD-DRAFT)

Flake Ice

Flake ice is small, hard bits of ice ideally suited for any “contact” presentation, such as displaying fish at the supermarket. It forms completely around the contact item and cools quickly. Because of its thin, flat shape, flake ice provides more surface area per ton than any other type of ice. It is often used in the processing of perishable food products when quick, efficient cooling is important. Such applications include seafood processing, poultry processing, meat processing, dairy processing, and even chemical manufacturing. The seafood industry is one of the largest users of flake ice worldwide.

Shaved Ice

This is a very fine ice that looks almost like snow and is often used for a specialty ice-based dessert product that is flavored. The ice is shaved from a block using an ice-block shaving machine. The popular vendor item known as the “snow cone” can be made from shaved ice but is more often made from crushed ice.

Block Ice

Block ice can vary in sizes from 10 lb ($6 \times 8 \times 10$ in) to as much as 300 lb ($10 \times 20 \times 40$ in). Blocks will last longer than cubes, so they are often used by campers and picnickers for coolers. For the same reason and because blocks take up less space, they are sometimes preferred for food processing. However, for the ice to be used effectively, it will still need to be crushed or ground into small pieces to make good contact with the food product. Another popular application for blocks is to make shaved ice.

87.4 ICE QUALITY

Generally, the ice machine will not freeze water like the simple ice cube tray you place in your freezer. The ice cube tray method will produce cloudy cubes as a result of air

Figure 87-5 Cube ice machine with cover removed to show evaporator and freezing cells.

bubbles trapped inside the ice. These bubbles come from the dissolved gases that can no longer stay in solution as the ice freezes. As the ice forms, it floats to the top, and this ice layer traps the bubbles within the cube. Commercial ice machines utilize systems in which water is circulated continuously through the freezing cell (Figure 87-5). This helps to eliminate air and flushes out any impurities. The cube should be completely clear.

TECH TIP

The speed at which water flows down the evaporator plate will directly affect ice purity, clarity, and hardness.

Temperature is critical because cold, pure, hard ice is denser, melts slower, and therefore lasts longer than softer ice. The amount of refrigeration effect also depends on the quality of the ice. Ice quality is measured in percentage of hardness, which is a measurement that represents thermal cooling capacity. Ice that has a higher percentage of hardness will have more cooling ability. Ice hardness is calculated by conducting a calorimeter test as specified in ANSI/ASHRAE Standard 29-2009.

Ice cubes and block ice will generally be within the 95 to 100 percent hardness range. Flake ice has more minerals carried over from the water during its formation, and more air is present. This reduces the overall hardness and cooling effect of flake ice to about 70 percent.

Figure 87-6 Location of the filter screen for a water inlet valve. (Courtesy of Manitowoc)

CODES AND STANDARDS

ANSI/ASHRAE Standard 29-2009, Methods of Testing Automatic Ice Makers, prescribes a method for testing automatic ice makers and includes information about testing procedures, instrumentation and apparatus required for testing, and a uniform method for calculating results.

87.5 WATER QUALITY

Water conditions vary widely from location to location. Cleaner water produces cleaner ice. It is important to have a good clean water supply that has filters or strainers that are regularly changed or cleaned. The filter screen location for a water inlet valve is shown in Figure 87-6. Ice machine problems are often a result of poor water quality. It goes without saying that poor-quality water will ruin the taste of any drink.

TECH TIP

Filtering systems that include sediment removal, activated carbon, and reverse-osmosis (R/O) units can be considered where water quality is questionable. Ultra-violet (UV) lamps can be used in the final stage to destroy any microbes that may remain. Although these systems provide very pure water, they can be expensive and should not normally be used where city tap water is available.

Testing Water

Water quality should be tested to determine if treatment is needed and what type of treatment would work best. Water treatment facilities often provide sample bottles and sampling instructions. The sample is taken and then sent to the facility to be analyzed. Kits are also available to test the water in the field, but the analysis is less comprehensive.

Suspended Solids

Suspended solids can usually be removed with a simple filter system. Mostly composed of minerals, these solids

will lead to cloudy ice cubes and a scaled-up evaporator surface. This scale reduces water flow through the system, reduces heat transfer, and will not allow the cubes to harvest from the evaporator plates. This is a common reason for ice machine freeze-up.

Dissolved Solids

During the freezing process, dissolved solids separate from the water and will lead to the same problems encountered with suspended solids. The difference is that dissolved solids are not removed with simple filtration systems. If dissolved solids are present, treatment is required to remove, reduce, or neutralize the minerals present. Hard water (water hardness) has greater concentrations of solids than soft water. Water softeners are used to produce an ion exchange that reduces the hardness of the water, making it less likely to produce scale.

TECH TIP

The filter flow rate is critical for proper sizing of a treatment system. Low water flow can lead to ice machine freeze-up. A properly selected filter should last from 4 to 6 months or longer before cartridges need to be changed.

Corrosion

Often pH is used to determine the acidity or alkalinity of the water. The pH scale ranges from 0 to 14. A neutral pH of 7 is desired. Readings below 7 are acidic. Acidic water can cause corrosion, while alkaline water usually has more scale-forming minerals.

Local municipalities have been adding higher levels of chlorine, chloramines, and sometimes chlorine dioxides to reduce bacteria in the water. Stainless steel ice-maker surfaces are susceptible to corrosion from the exposure to chlorine gas. These gases stick to the wet surfaces to form hydrochloric acid. This results in a rust-colored corrosion and pitting of the stainless steel.

Slime Buildup

Slime buildup results from the growth of bacteria and fungi and occurs partly due to the moist conditions present in an ice machine. When the bin door is opened for ice removal, airborne bacteria will enter the bin cavity. The bacteria will adhere to the wet surfaces on the evaporator. This buildup can lead to odors and is a health concern. Chlorine sanitizing solutions and tablets should be used on a regular basis to keep bacteria and fungi growth in check.

87.6 CUBE ICE MACHINE OPERATION

Cube ice machines all have the four basic components of the refrigeration cycle: compressor, condenser, metering device, and evaporator. A cross-sectional view of an ice machine is shown in Figure 87-7. The evaporator has individual

cells built into it, similar to an ice cube tray (Figure 87-8). A water pump is used to distribute the water evenly across the cells to allow the freezing process to begin (freeze cycle) (Figure 87-9). When the ice is formed to the proper thickness, a harvest cycle is initiated to release the cubes from the cells and to be collected in the ice bin (harvest cycle). When the ice bin is full, the ice machine will stop producing ice.

Freeze Cycle

Evaporators are made of copper to allow for good heat transfer. They are tin plated or sandwiched between stainless steel plates for protection against corrosion (Figure 87-10). Evaporators can be either vertically or horizontally positioned. The operation allows for a fixed amount of water supplied from a reservoir to circulate continuously through the freezing cells to form ice smoothly on the cold surfaces. The water is directed evenly to the cells by a water-distribution tube (Figure 87-11). The pure water freezes first and impurities are washed down and away from the cells. This circulation of water that allows the ice to grow from the freezing surfaces outward also eliminates the formation of air bubbles.

There is often a short period for chilling the evaporator coil at the beginning of the freeze cycle (approximately 30 seconds) before the water begins to circulate. This allows the ice to immediately begin forming once the water contacts the cold surfaces. The reservoir will have a float switch or water-level probe that terminates the freeze cycle when the water level is low, indicating that the ice cubes have been formed.

An ice-thickness sensor can also be used to determine when the ice has reached its maximum thickness (Figure 87-12). This will be more accurate than relying merely on the water level in the reservoir. When the ice reaches the proper thickness, the freeze cycle is terminated. There is typically a slight delay (several seconds) before the freeze cycle is terminated to ensure that the ice-thickness sensor is accurate and is not being prematurely activated by splashing water.

Harvest Cycle

The term *harvest* is a throwback to the days when ice was “harvested” from lakes and rivers. When the ice is properly formed, it needs to be released from the freezing cells. The harvest cycle is initiated either when the reservoir float switch indicates a low water level or when the ice sensor determines the proper ice thickness has been reached. A hot-gas solenoid valve will direct the hot discharge gas from the compressor directly into the evaporator coil rather than to the condenser (Figure 87-13). This method causes a rapid heating of the freezing cells, allowing the cubes to be released to drop and collect in the ice bin located directly below. Some ice machines have water assist. A separate loop of water circulation aids in releasing the ice from the freezing cells. The harvest cycle will continue until a thermistor (evaporator temperature probe) measuring evaporator temperature is satisfied that the proper harvesting temperature has been reached.

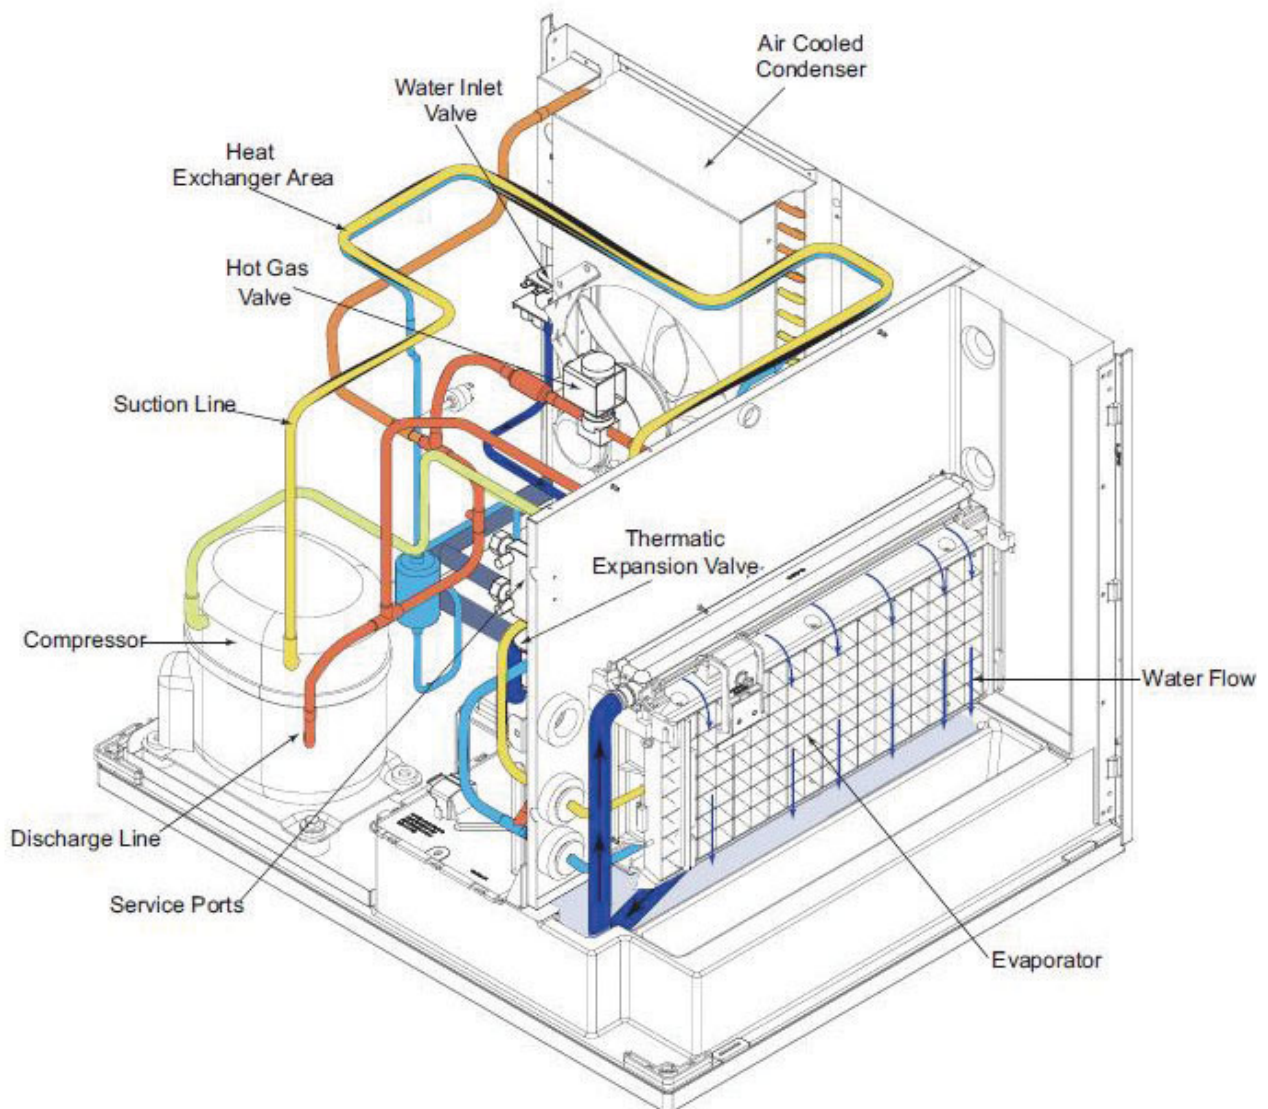

Figure 87-7 Cross-section of a cube ice machine. (Courtesy of Scotsman Ice Systems)

Figure 87-8 Evaporator and freezing cells.

Figure 87-9 Water-circulation pump.

Figure 87-10 Ice machine evaporator.

TECH TIP

Have you ever had trouble at home with breaking, fragmented cubes that are difficult to remove from an ice cube tray? Place the entire tray under running warm water for several seconds and you will find the cubes much easier to remove. In a similar manner, some harvest cycles use water assist. The circulating water will help to release the cubes from the freezing cells.

Reservoir and Float Switch

The reservoir is filled by a water inlet valve. A water pump drawing from this reservoir will circulate the water across

(a)

(b)

(c)

Figure 87-11 (a) Ice machine with location of water-distribution tube shown; (b) water distribution tube; (c) removing a water-distribution tube for cleaning. (Courtesy of Manitowoc)

Figure 87-12 Cross-section of ice machine showing location of ice thickness sensor. (Courtesy of Scotsman Ice Systems)

the freezing cells. Typically, when the reservoir is full, the freezing cycle will begin. The level in the reservoir is determined by a float switch or a level probe. The evaporator is generally allowed to chill for a brief period before the water begins to circulate.

Since there is a fixed amount of water in the reservoir, the cubes should be fully formed when the water level becomes low. A common float that rides up and down with the water level is attached to a switch (Figure 87-14). This will determine if the level is at maximum, minimum, or somewhere in between. A water-level probe does not rely on a float but instead on the conductivity of the water (Figure 87-15). With either type of level indicator, the cycle process is still similar.

When the reservoir is low, the ice cubes should be formed, and the harvest cycle is initiated. The harvest cycle will be terminated when the evaporator has reached a sufficient temperature to ensure that the formed ice has been released. The end of the harvest cycle will allow for the reservoir to be refilled by the water inlet valve. An excess amount of water is supplied and overflows a standpipe located in the reservoir. This excess water “flushes” out the impurities that have collected in the water from the previous freeze cycle.

When the reservoir is full, the evaporator will pre-chill, and then the freezing cycle will begin once again. This cycle of freezing and harvesting will continue until the ice bin is full.

Ice Bin Controls

The ice bin is where the ice is collected and stored for later use (Figure 87-16). The ice drops from the freezing cells through the ice chute into the ice bin (Figure 87-17). There are different types of controls to determine when the ice bin is full. A thermostatic capillary tube (ice-level probe) attached to a pressure switch can be mounted in the ice drop zone (Figure 87-18). When the bin is full, ice touches the thermostatic bulb and the pressure inside the bulb drops. This opens the contacts in the pressure switch to shut the ice machine down.

A mechanical-type bin control may consist of a proximity switch and a paddle. When the bin is full, ice pushes the paddle away from the proximity switch and the unit shuts down. Another type of mechanical bin control utilizes a curtain that opens to allow the newly formed ice to pass through to the bin during the harvest. At the edge of the curtain is a switch (Figure 87-19). If the curtain opens and closes during

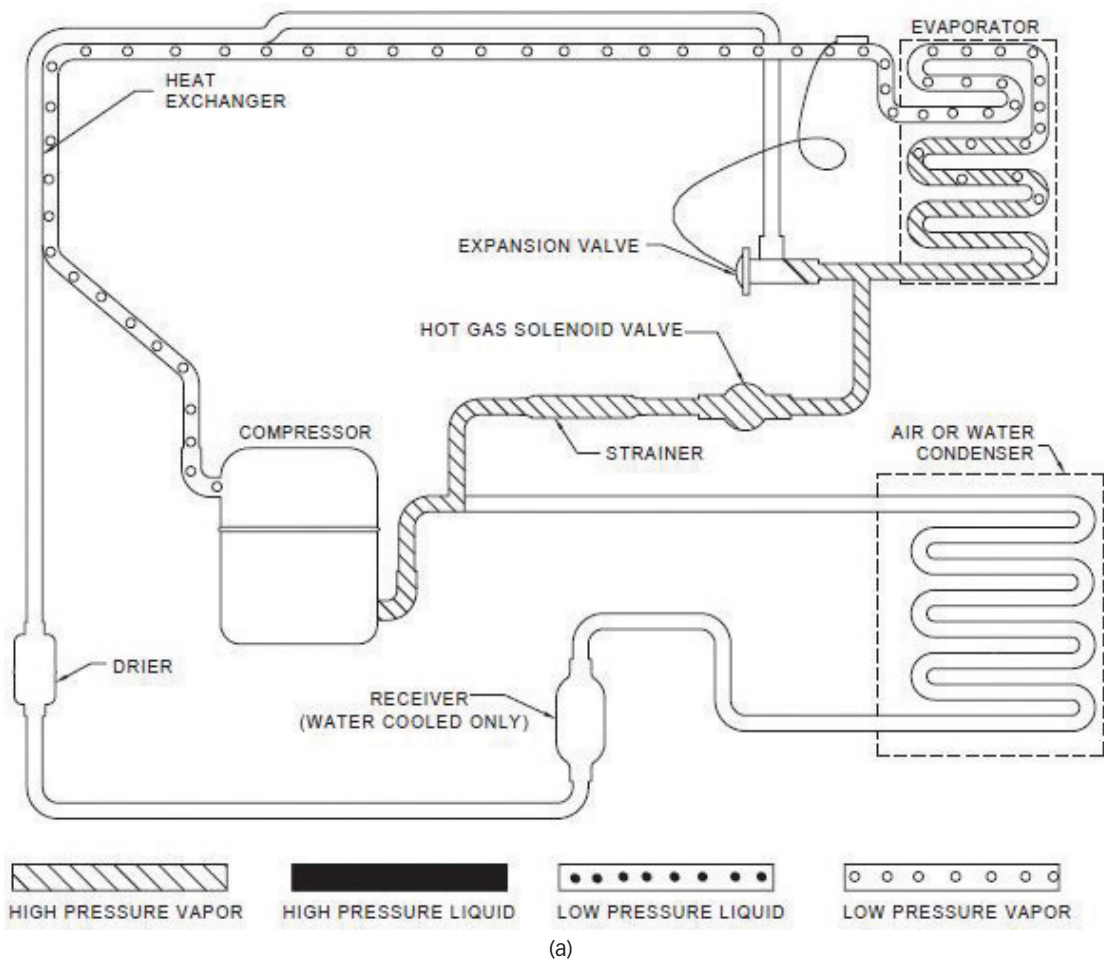

Figure 87-13 (a) Harvest cycle (Courtesy of Manitowoc); (b) ice machine schematic showing location of hot-gas valve. (Courtesy of Hoshizaki Technical Support)

Figure 87-19 (a) Ice curtain; (b) ice curtain switch.

the harvest cycle, the controller will start a fresh freeze cycle. If the curtain remains open during harvest, indicating the bin is full of ice, the controller will shut the machine off.

Photo-Electric Eyes

Bin level control does not protect against ice machine malfunction but only shuts the unit down when the bin is full of ice. Some ice machines use photo-electric eyes to detect ice as it is made. If no ice production is sensed within a set period of time, the unit will shut down. If this fault is repeated consecutively, the machine may shut down and

need to be manually reset. There is a delay programmed into the controller to allow time for the machine to begin making ice when it is first started. This type of system protects the ice machine from damage that could occur from freeze-up and other such problems.

87.7 FLAKE ICE MACHINES

Unlike cube ice machines that go through freezing and harvesting cycles, flake ice making is a continuous process. Most flake ice machines utilize a vertical cylindrical, tube-shaped stainless steel evaporator (Figure 87-20).

(b)

Figure 87-20 (a) Flake ice machine operation (Courtesy of Scotsman Ice Systems); (b) evaporator and auger; (c) (see next page) cylindrical, tube-shaped stainless steel evaporator.

(c)

Figure 87-20 (Continued)

Water flows from a reservoir to the evaporator, where it comes into contact with the stainless steel freezing surfaces and freezes immediately on contact. A float switch in the reservoir maintains the water level in the evaporator. A slow-turning spiral-fluted auger located within the evaporator forces the crystalline ice formed on the inside of the evaporator to crack and break away. The flake ice moves

upward and out through the top of the evaporator following the rotation of the auger.

Small holes sometimes called breakers at the top of the evaporator tube help to squeeze out any remaining water before it passes to the ice chute and on to the ice bin. An ice sweep revolves with the auger at its top to help move the ice into the ice chute (Figure 87-21). In addition to the typical bin controls described with cube ice machines, a photo-electric eye may be located in the base of the ice chute to detect the production of ice.

Auger Seal

The auger will be driven by an electric motor through a gearbox arrangement. A positive seal prevents water from entering the gear box and oil from entering the ice. It is important for the auger to be perfectly straight inside the cylinder so that it does not wobble. The auger flute should not contact the inner wall of the stainless steel evaporator. An auger seal and its removal are shown in Figure 87-22.

Safety Devices

Due to their design and application, flake ice machines have some additional safety devices. A low-water safety protects against dry operation or freeze-up in the evaporator due to low water flow. A safety in the gear motor circuit will not allow the refrigeration system to operate unless the auger

(a)

(b)

Figure 87-21 (a) Flake ice machine components showing ice sweep (Courtesy of Scotsman Ice Systems); (b) ice sweep.

REMOVAL OF THE WATER SEAL

To Replace the Water Seal:

(a)

(b)

Figure 87-22 (a) Removing seal for flake ice machine auger (Courtesy of Scotsman Ice Systems); (b) flake ice machine auger seal.

is rotating. A safety in the gear motor circuit will not allow the refrigeration system to operate if there is excessive load on the auger, typically indicated by a high amperage draw.

87.8 ICE PRODUCTION

Ice production will decrease during periods of warmer weather when outside and incoming water temperatures are high. Because of this, the actual ice production per day will vary and must be cross-referenced to the manufacturer's performance data chart. The measured ice production, ambient temperature, and inlet water temperature must be applied to the chart, and ice production should fall within $\pm 10\%$ of rated capacity. For the best accuracy, ice production checks should be performed during a normal freeze cycle, not just after the machine has been opened for service or shut down.

For cube ice machines, the entire freeze cycle must be timed (total amount of minutes) from the beginning of one cycle to the beginning of the next. To determine the number of cycles per day, divide 1,440 (the total minutes in a day) by the total minutes that were timed for the cycle. All the ice made during that cycle must be collected and weighed. Multiply the weight of the collected ice by the number of cycles per day to calculate the total pounds of ice produced per day.

For flake ice machines, collect all of the ice made for a 10-minute period. The ice collected must be weighed. Multiply the weight of the ice collected by 144 to calculate the total pounds of ice produced per day.

TECH TIP

To calculate the total number of minutes per day, multiply 24 hours by 60 minutes per hour to arrive at 1,440 minutes per day.

87.9 CLEANING, SANITIZING, AND FLUSHING

Proper maintenance includes keeping the ice machine clean. This will ensure good ice quality, such as taste and size. Cleaning also helps to keep up the ice-making capability of the machine for maximum ice harvest.

Cleaning

Maintaining water quality is an important maintenance item for ice machines. Filters and strainers need to be regularly cleaned and replaced, and the ice machine should be entirely cleaned and sanitized at least once a year. In areas where the water quality is poor, more frequent cleaning will be needed. If parts fail due to calcium or scale buildup, they may not be covered under the machine's warranty if proper cleaning procedures were not followed. There are a number of different cleaning solutions available. It is important to review the MSDS for the cleaner you are using. These should be available when purchasing the product or downloaded online.

Figure 87-23 (a) Ice machine instructions for cleaning cycle; (b) switch for cleaning ice machine; (c) valves must be manually repositioned when cleaning this ice machine.

SAFETY TIP

Cleaning solutions used for ice machines must be used correctly, as they are mostly acid solutions. Check the MSDS for the solution that you are using. Whenever you handle solutions, wear chemical splash goggles and chemical-resistant impervious gloves. Use the solutions in a well-ventilated area.

Many ice machines have a cleaning cycle (Figure 87-23). To clean an ice machine, all the ice must be removed from the bin so that the cleaning solution will not contaminate the ice. The water should be turned off and the sump tank drained. The cleaning solution (descaling solution) is mixed with warm water in the correct ratio and poured into the sump tank. When the unit is turned on to the cleaning cycle, the cleaning solution will flow through the system and should be circulated until the unit is clean.

A nylon bristle brush that fits tightly down the channels on the evaporator may be used when the evaporator is extremely dirty and simple flushing is insufficient to remove the built-up scale. Be careful not to damage the evaporator plates. Individual components such as spray tubes and float switches can be taken apart and allowed to soak in solution. The inlet water valve should be taken apart and cleaned along with its strainer.

SAFETY TIP

Augers used for flake ice machines may need to be removed and cleaned. After the auger is removed and dried, it should appear bright and shiny. Be careful when handling the auger because it will have sharp edges.

Sanitizing

Most cleaning solutions will not kill the algae and bacteria that can develop on the ice machine. A separate sanitizing solution or sanitizing tablets should be used. The sanitizing solution will be circulated in the same manner as the cleaning solution. Do not mix the sanitizer with the descaling solution. Sanitizing should be performed regularly and after every repair or replacement of parts. After cleaning and sanitizing, the machine should be thoroughly rinsed and allowed to air-dry before renewed operation.

SAFETY TIP

Never mix cleaning solution (descaling solution) and sanitizing solution together. Mixing the two solutions can create a strong chlorine gas that is difficult to breathe.

Flushing

With cube ice machine design, the water flows across the evaporator plates and the minerals and contaminants are washed away so as not to collect on the evaporator surfaces. This leads to higher and higher concentrations of solids for the water that returns to the reservoir (sump). Periodic flushing of the reservoir reduces the buildup of scale-forming solids. To reduce this buildup, a standpipe is located in the reservoir that regularly overflows, thus flushing out the contaminants.

In addition to a standpipe, a periodic flush cycle controlled by a timer will cycle the unit down and open a flush valve to allow the complete water system to drain (Figure 87-24). This is important for flake ice machines that utilize an auger rather than evaporator plates. Flake ice machines will have greater concentrations of scale buildup as compared to cube

Figure 87-24 Water drain valve. (Courtesy of Manitowoc)

ice machines. Since solids collect near the bottom of the auger, a complete draining and flush of the system is required.

SERVICE TIP

A strange sound coming from a flake ice machine as a high-pitched squeak or squeal in combination with low production and soft, mushy ice is an indication of a dirty evaporator.

Some machines have built-in features that provide for a regular automatic cleaning or sanitizing cycle. The number of ice-making cycles is tracked by the machine, and the appropriate cycle is initiated when the limit of ice-making cycles is reached. This reduces the need to manually clean the machine as frequently.

87.10 COMPRESSOR DISCHARGE (HEAD) PRESSURE

The importance of operating with a correct discharge pressure for an ice machine is not very different from any other refrigeration system. Proper refrigerant liquid-line pressure

is required to maintain the necessary pressure drop across the metering device. Just as in any typical refrigeration system, low discharge pressure can result from a low refrigerant charge, too much condenser cooling, and a restriction in the liquid line. High discharge pressure is often the result of inadequate condenser cooling. Troubleshooting these conditions follows the normal progression for diagnosis. However, cube ice machines are different in that a hot-gas harvest cycle is employed to release the newly formed ice.

Hot-Gas Harvest Cycle

Low discharge pressure will severely affect the harvest cycle for cube ice machines. This can occur at low ambient temperatures when the condenser has too much cooling. Cube ice machines will have a hot-gas valve open during the harvest cycle to allow the discharge from the compressor to directly enter the evaporator. It is the heat from the gas that melts the cubes just enough to cause them to release from the freezing cells and fall into the ice bin. If the discharge pressure is too low, the hot gas will not properly flow through the evaporator and the harvest cycle will not complete.

To artificially increase the discharge pressure during low ambient conditions, headmaster controls are often used. The headmaster is a valve with three different ports. One connects to the condenser, one to the receiver, and

Figure 87-25 Head pressure control valve. (Courtesy of Hoshizaki Technical Support)

one directly to the discharge line (Figure 87-25). Normally the refrigerant flows from the compressor to the condenser to the receiver. If the discharge pressure begins to drop, some refrigerant will by pass the condenser and go directly to the receiver as controlled by the headmaster valve (Figure 87-26). Other methods for controlling discharge pressure include regulating the condenser fan speed for air-

cooled condensers and regulating the condenser-cooling water flow for water-cooled condensers.

TECH TIP

The evaporators on cube ice machines continually switch back and forth between freezing cycles and harvest cycles. The evaporators are specifically designed to withstand the resulting effects of contraction and expansion. However, if an ice maker's controls are malfunctioning and extended periods of harvesting (hot gas) result, the evaporator can be damaged.

Remote Condensers

The main reason for high discharge pressure is reduced heat transfer in the condenser. This can be a particular problem for ice machines that are located in high-temperature areas. Sometimes restaurants and cafeterias locate the ice machine near the cooking area for easy access to the ice. This can result in excessive ambient temperatures, and the ice machine condenser will operate poorly. Under these conditions, the ice production will decrease. Even if the unit works

REMOTE MODELS

Figure 87-27 Ice machine with remote condenser located outside. (Courtesy of Manitowoc)

somewhat satisfactorily, its useful life will be reduced. When installing an ice machine located in a high ambient area, you should advise the customer as to the benefits of a remote condenser (Figure 87-27). Although the initial cost is greater, the unit will perform better, produce more ice, and last longer.

87.11 TROUBLESHOOTING ICE MACHINES

Troubleshooting ice machine problems can often be particularly annoying. This is because you need to address not only the refrigeration components but also the many other mechanical components of the machine. The first step is to gain an understanding of basic refrigeration system troubleshooting. Next, become familiar with how ice machines operate. Finally, refer to the manufacturer's service information for the particular unit that requires attention. Most ice-machine manufacturers provide very good troubleshooting guides and service manual information.

Freeze-ups

Freeze-ups are the most frequent service problem associated with ice machines. Always check the simplest things first. A dirty evaporator causes the ice to stick to the freezing cell so that it may not release during harvest, and during the next freeze cycle the ice continues to build up (bridges). Too much water flow will cause the ice to build up and bridge downward over all the cells. A partially blocked water-distributor tube will lead to bridging of some cells and a lack of ice in others (Figure 87-28). This is because some cells are receiving too much water while others not enough.

An improperly mounted ice-level probe or mechanical level control for an ice bin will cause the ice to back up. When the ice is released from the freezing cells during harvest, it has no place to go. Since every freezing cycle distributes additional water, the evaporator will freeze into a block of ice. A freeze-up will also result from problems pertaining to the flow of hot gas that will affect the harvest cycle. Table 87-2 provides a list of some possible common problems.

Figure 87-28 Water-distribution tube may need to be cleaned periodically.

Table 87-2 Possible Causes of Ice Machine Freeze-up

Condition	Possible Cause
Ice sticks and does not release during harvest and builds up	Dirty evaporator
Too much water bridges cubes together	Inlet water valve leaking
Bridging on some cells with lack of ice in others	Blocked distribution tube
Ice backs up into evaporator section	Ice bin control faulty
No hot gas through evaporator for harvest cycle	Hot-gas valve stuck closed
Not enough hot gas through evaporator for harvest cycle	TEV leaking during harvest
Not enough hot gas through evaporator for harvest cycle	Low discharge pressure

Poor-Quality Ice and Production

Cloudy ice is often the result of poor-water quality and dirty evaporator surfaces. A decrease in ice production can result from a low water flow. Inlet control valve screens and

Table 87-3 Possible Causes of Poor Ice Quality and Low Production

Condition	Possible Cause
Cloudy ice	Poor water quality
Small cubes and lack of production	Low inlet water flow
Small cubes and lack of production	Refrigerant undercharge
Uneven ice formation	TEV superheat
Small cubes and lack of production, frequent trips	High discharge pressure
Small cubes and lack of production	Blocked metering device
Lack of production	Faulty evaporator thermistor

inlet filters should be checked. A lack of ice production can result from a refrigerant undercharge, which should coincide with a low suction and discharge pressure. Improper TEV superheat can affect cube quality. High superheat can affect the cubes located toward the outlet of the evaporator, making them smaller. Low ice production can also result from high discharge pressure or a partially blocked metering device. A faulty evaporator thermistor can lead to extended harvest times and potentially cause damage to the evaporator. Table 87-3 provides a list of some possible common problems.

Control Systems

Electronic control systems consist of a central controller that receives inputs from assorted sensors that monitor the status of such levels as ice thickness, water level, water temperature, and discharge temperature (Figure 87-29). Controllers operate from a low-voltage power supply and use the input from sensors to switch relays on and off. Most mechanical relays found on older units have been replaced by solid-state relays. The relays operate motors and solenoids that require line voltage.

Control boards utilize multilayered circuitry to improve safety protection and help with service diagnosis. LED lights help to troubleshoot a problem. These lights come on during sequences of each cycle, such as fill, harvest, freeze, and pump out (Figure 87-30). When troubleshooting, the LEDs should light in the proper sequence of operation.

Faults can be identified by a lit fault LED. Some units have alarm codes or beeps to indicate such faults as high temperature, long harvest cycle, long freeze cycle, shorted connection, open connection, low voltage, and high voltage. Some units store fault codes that can be later recalled to provide a brief history of the machine's condition to help troubleshoot problems.

Controller

Figure 87-30 LED lights on an ice machine controller.

gas, while flake ice machines continuously produce ice and utilize a rotating auger. Whenever troubleshooting these machines, try to determine if the malfunction is refrigerant related. Most manufacturers provide detailed service manuals and troubleshooting guides that are unit specific. Controller LED fault code indicators will help to diagnose problems. Take the troubleshooting sequence step by step. Look at the symptoms first before jumping to conclusions, because there are no such things as “phantom” freeze-ups. There is always a logical reason for an operating problem.

WORK ORDERS

Service Ticket 8701

Customer Complaint: Ice Machine Freeze-up

The service technician is told by the customer that the ice machine has stopped producing ice. Upon inspecting the machine, it is found that the evaporator had a freeze-up. The LED display on the controller indicates the unit shut down because the freeze cycle lasted less than 5 minutes for three consecutive cycles. This is because the ice was not releasing from the freezing cells and the ice-thickness sensor was terminating the freeze cycle.

UNIT 87—SUMMARY

There are many different models and types of ice machines. The most common types are cube ice and flake ice machines. Both types utilize the standard refrigeration cycle. Cube ice machines have a harvest cycle that requires hot

almost immediately at the beginning of each cycle. The first step taken is to allow the evaporator to thaw out completely before restarting. Once started, the machine seems to operate through a number of cycles as normal. The technician suspects that something has stopped the ice from releasing normally. The evaporator surfaces appear clean and the hot-gas solenoid and water-level probes seem to be working normally. Checking the ice bin probe, the technician finds that its capillary tube has become kinked. The technician replaces the ice bin probe. Evidently, the kinked capillary tube provided a false signal, allowing the ice to back up from the ice bin, which led to the freeze-up.

Service Ticket 8702

Customer Complaint: New Ice Machine

The restaurant manager tells the technician that she wants to replace her ice machine. It is only a few years old but it had problems right from the start. It never produced enough ice and the machine tripped out frequently. She would never buy that brand again. The technician is very familiar with the brand and knows that it is a reliable machine. The machine is located in a corner of the kitchen, and there is little air flow for the condenser. However, this is about the only place the machine could be located due to the limitation of space. Because the manager is familiar with the operation of that unit, the technician suggests a similar model of the same brand ice machine but one equipped with an outside condenser. This will cost more but will provide for better operation and longer life. The manager is at first skeptical but decides to take the technician's recommendation. A month after the installation, the technician checks with the manager to find that she is very happy with the new machine and always has a good supply of quality ice.

Service Ticket 8703

Customer Complaint: No Ice

The bartender tells the technician that the ice machine shuts down and is not making any more ice. Checking the controller, the technician finds that the LED fault indicator for the harvest cycle is lit. For protection, the unit automatically shuts down when the harvest cycle exceeds 20 minutes. The long harvest could be due to ice sticking to the freezing cells and not releasing because the evaporator is dirty. However, if the cycle goes on for an extended period, the evaporator could reach a temperature over 120 degrees, and this would

also lead to a trip. But the evaporator high-temperature LED fault indicator is not lit. Checking the maintenance records, the technician discovers that the machine was recently cleaned and the water filter changed. So instead of cleaning the machine, the technician manually resets it and places it into the harvest cycle. The hot-gas solenoid does not seem to be functioning because the line between it and the evaporator is not hot. The machine is shut down and the power to the unit secured. The solenoid coil is removed from the hot-gas valve and checked with a multimeter. The reading shows an infinite resistance, indicating an open coil. The technician replaces the coil and restarts the machine. It now begins to harvest and cycle normally.

UNIT 87—REVIEW QUESTIONS

1. List eight applications for commercial ice machines.
2. How much ice will a 12-oz drinking cup approximately hold?
3. About how many dice ice cubes would it take to equal 1 lb of ice?
4. How is crushed ice made?
5. Why is flake ice ideally suited for any "contact" presentation, such as displaying fish at the supermarket?
6. Can ice machine cleaning solution be mixed with sanitizing solution?
7. Why is the flushing cycle important for flake ice machines?
8. What is the purpose of the auger seal on a flake ice machine?
9. List three safety devices used for flake ice machines.
10. What might cause a high-pitched squeak or squeal in combination with low production and soft, mushy ice in a flake ice machine?
11. Why would it be desired to increase the head pressure for a cube ice machine?
12. How can discharge pressure for a cube ice machine be artificially increased?
13. What could cause frequent tripping on high-discharge pressure and poor ice production?
14. What would happen if the ice machine had a partially blocked water distributor tube?
15. What could cause ice to build up and bridge downward over the freezing cells?
16. What could happen if there were a burned-out solenoid on a hot-gas valve?
17. What could cause ice to build up in the ice bin?
18. List two things that might lead to a decrease in ice production.
19. Why might an ice machine produce cloudy ice?
20. What type of fault could lead to extended harvest times?

UNIT 88

Troubleshooting Refrigeration Systems

OBJECTIVES

After completing this unit, you will be able to:

1. explain the different methods to electrically troubleshoot a refrigeration system.
2. explain how to troubleshoot a defective compressor.
3. explain how to troubleshoot a defective start relay.
4. explain how to troubleshoot a defective capacitor.

5. explain how to troubleshoot metering devices.
6. explain how to troubleshoot common evaporator problems.
7. explain how to troubleshoot common condenser problems.
8. explain how to search for leaks in a refrigeration system.

88.1 INTRODUCTION

Patience is a requirement when troubleshooting refrigeration systems. It is important to take the time necessary to properly diagnose a system problem, as rushing to a quick diagnosis often leads to misdiagnosing the root cause of the problem.

A good service practice is to spend some time speaking to the customer before looking at the system. Listen to the customer's complaints and then ask some pertinent questions about the system, such as the following:

- How old is the unit?
- When was it last repaired, and what was done?
- Has the unit been working OK up until the time of the breakdown?
- Have you noticed any strange sounds or erratic operation lately?

After speaking with the customer, it is time to gather some information about the system. Conduct a visual inspection of the system and look for any obvious system problems. This is another important part of the troubleshooting process. During the initial visual inspection try to determine the following:

- Unit model and serial numbers
- Required supply voltage and phase
- Current ratings of motors
- Full load amps for most motors
- Rated load amps (RLA) for compressor motors
- Type of metering device used
- Type of refrigerant in the system
- Condition of the evaporator and condenser coils
- Overall condition of the equipment

It may be necessary to remove panels on the equipment to see everything. A crucial part of the initial inspection is the examination of the evaporator and condenser coils. An iced-up evaporator coil and dirty condenser coil are two common problems that can easily be identified during a visual inspection. The cause may not be as apparent, but the symptom is easy to discover.

Identifying the refrigerant type helps to determine the correct operating pressure when it comes time to install a set of service gauges on the system to read its working pressures. Finding the correct supply voltage and whether it is a single- or three-phase system will also help when testing the circuit.

Another part of a visual inspection is to look for any oily pipes or parts, which is usually a good indication of a refrigerant leak. Also carefully (it may be hot) feel the head of the compressor to see if it is cold, warm, or hot. This helps determine if the compressor is the cause of the problem. For example, if the compressor is extremely hot and not running, it may be off due to an overload. You may want to start troubleshooting there to find out why this has happened.

Visually inspecting all the major components of a system takes a little extra time, but it is time well spent and is necessary to efficiently troubleshoot any refrigeration system.

SAFETY TIP

Taking shortcuts on a job may save time but may cause a technician to work in an unsafe manner. This is not a wise tradeoff. Do not take any shortcuts that may cause you to work in an unsafe manner. It is simply not worth the few extra minutes you may have gained.

88.2 ELECTRICAL TROUBLESHOOTING

Electrical troubleshooting can be divided into two areas: (1) electrically diagnosing controls (switches, relays, and contactors) and (2) electrically diagnosing loads (coils, fan motors, and compressors).

There are three major tools commonly used to troubleshoot the various electrical components of a refrigeration system: (1) voltmeter, (2) ammeter, and (3) ohmmeter. Each measures a different electrical characteristic in a circuit and is needed to properly diagnose an electrical fault within a system. Many technicians will use a multimeter, as shown in (Figure 88-1), to measure all of these electrical characteristics.

Figure 88-1 A digital multimeter used to measure various electrical characteristics of a circuit.

SAFETY TIP

When replacing or repairing any electrical components, always verify that the voltage source is truly disconnected from the circuit. Test the circuit for the presence of voltage with some type of voltmeter or voltage indicator. Do not solely rely on the electrical disconnect to ensure the voltage is disengaged. Always verify this yourself.

A voltmeter measures electrical potential (voltage) at a switch or a load (such as a motor or the coil of a contactor). For a load to operate properly, the correct voltage must be applied. Most units will have the required applied voltage stamped on a clearly marked nameplate. If a load is not energized, one of the first steps in the troubleshooting process is to determine if the proper voltage is applied to the nonenergized load. For most loads, the applied voltage must be within ± 10 percent of the nameplate voltage. If no voltage or the incorrect voltage (outside the ± 10 percent tolerance) is present at a load, then the problem lies in the voltage supply, controls, or wiring leading to that load. When checking the applied voltage to a load, always measure the voltage at the load and not at an electrical junction before the load. There may be an issue with the wiring leading to the load, so it is more accurate to measure the applied voltage directly there.

A voltmeter can also be used to check the operation of the various electrical controls in a circuit. Electrical controls fail in one of two ways: they fail to close or they fail to open. A voltmeter can be used to determine whether a control is electrically open or closed by measuring the line

voltage across the control's contacts. A measured voltage indicates that the contacts are electrically open. If the contacts should be closed, then the circuit problem lies in the control.

SAFETY TIP

When working on electrical circuits, safety should always be first on your mind. Electrical circuits should always be de-energized before repairing or replacing any electrical component or wiring. De-energize at the system's disconnect and then follow standard lockout/tag-out procedures.

A zero measured voltage would seem to indicate the control is closed. However, this is not always true. The absence of a line voltage across a contact does not always indicate the contact is closed. If two or more controls wired in series are electrically open in a circuit, then there will not be a line voltage drop across their contacts. Therefore, this method of electrically troubleshooting a control is not always reliable.

A more reliable method of electrically troubleshooting controls is a procedure referred to by many technicians as hopscotching. This allows a technician to easily isolate an open electrical component. First, attach one probe of a voltmeter to a common point in the circuit (Figure 88-2). The blue probe is attached to the L2 leg of the circuit and will stay attached at this point during the process. This is an electrically common point for all the loads in the circuit. Now the red probe can be moved around the circuit to help determine which switch is electrically open or closed.

Here is an example of the process. As shown in Figure 88-2, the red probe of the voltmeter is initially connected before the CR contact and should read line voltage, which is 115 V in our example. When the red probe is moved to point 6 on the diagram, 115 V should again be read on the voltmeter if the CR contact is electrically closed. If the voltmeter reads 0 V, the CR contact is electrically open. This process can be repeated for all of the switches in the circuit. If line voltage is read before and after the switch, the switch is

Figure 88-2 Hopscotching an electrical circuit.

Figure 88-3 A digital clamp-on ammeter used to measure the amperage drawn of the load in a circuit.

electrically closed. If line voltage is read before but not after the switch, the switch is electrically open.

An ammeter is another effective troubleshooting tool. A clamp-on ammeter is shown in Figure 88-3. It is used to measure how much current a load is drawing. This enables a technician to verify that a load is electrically energized. If a load is drawing current, it is electrically energized. However, the total amount of current being drawn will indicate whether the unit is operating properly. If a load is drawing current outside the specifications of the manufacturer of the component, then there is a problem with either its operation or application.

Always check with the manufacturer of the component to determine its correct operating current range. For many (but not all) fan motors, the current drawn by the fan motor should be within a range of $-25\%/+10$ percent of its nameplate full load amperage rating. The amperage drawn by a compressor varies depending on its applied suction, discharge pressure, and applied voltage. Compressor manufacturers will publish the correct operating current draws for their compressors.

An ohmmeter is another useful tool for electrically troubleshooting electrical components. It can be used to check both controls (switches, relays, and contactors) and loads (coils, fan motors, and compressors). An ohmmeter measures the resistance of an electrical component. When using an ohmmeter, it is necessary to electrically remove the component from the circuit. This means that if a voltage is applied to the circuit, it needs to be de-energized and the wiring connecting the component to the electrical circuit removed. If voltage is applied to an ohmmeter, the meter could be damaged.

An ohmmeter can be used to check whether a control's contact is electrically open or closed. Once the component is disconnected from the circuit, the leads of an ohmmeter

can be placed across the control's electrical contacts. If the ohmmeter measures a resistance of approximately $0\ \Omega$, the contacts of the control are closed. If the ohmmeter measures an infinite resistance (OL) across the control's contacts, the contacts are open.

When using an ohmmeter to check the condition of a load, the leads are placed across the windings of the load. If the measured resistance agrees with the manufacturer's specifications, the windings of the load are OK. If a $0\ \Omega$ resistance is measured across the windings of the load, the windings are shorted. If an OL value is measured across the windings, the windings are open.

88.3 MECHANICAL REFRIGERATION TROUBLESHOOTING

Troubleshooting the mechanical side of a system involves analyzing or investigating the refrigerant flow either throughout the entire system or through any of the components. This requires being able to determine the refrigerant's pressure and temperature at various locations throughout a system.

When analyzing the entire system, the actual refrigerant conditions at various locations in a system are compared to the design conditions of a properly operating system. This will normally allow a technician to determine a system's defect. For example, if a system is discovered to be operating with both lower than normal suction and discharge pressures, and the superheat value of the refrigerant leaving the evaporator is higher than normal with a lower than normal subcooling value leaving the condenser, a technician can determine that the system has a low refrigerant charge.

Many times a technician will need to analyze the process through a component such as the compressor, condenser, or evaporator. This requires an understanding of the component and how it is designed to function in a system. For example, a refrigeration compressor is designed to pressurize a low-pressure refrigerant vapor to a higher-pressure refrigerant vapor. If a compressor is electrically operating but fails to sufficiently increase the pressure of the refrigerant from its inlet to its outlet, the compressor is mechanically defective, and more than likely the compressor will need to be replaced.

In general, a technician can analyze the operation of the evaporator as well. If the superheat value of the refrigerant leaving an evaporator is higher than normal, the evaporator is starved for refrigerant. If the superheat value of the refrigerant is lower than normal, the evaporator is flooded with refrigerant. Finding the reason why the evaporator is either being starved or flooded, however, will require looking at the entire system and analyzing other conditions.

When analyzing the condition of the refrigerant throughout a system or through a system component, a technician must allow the pressures and temperatures of the refrigerant to stabilize upon restarting if the system has been off. When troubleshooting, it is a good service practice to let a system run for about 10 minutes before recording any of the system's pressures or temperatures.

88.4 TROUBLESHOOTING A DEFECTIVE COMPRESSOR

Replacing a compressor on a refrigeration system is never an easy or inexpensive task. If a compressor is found to be defective, every effort should be made to verify that a correct diagnosis is made. Sometimes compressors that have been changed out in the field are later found to be operational.

Compressor problems can be divided into two groups: mechanical and electrical. Mechanical defects are problems that affect the operation inside the compressor, such as blown valve plates, a broken crankshaft, or worn pistons. These defects will either cause a compressor not to pump any refrigerant or pump to below its rated capacity.

It is generally easy to determine if a compressor is not pumping adequately. At start-up, verify that the compressor is electrically energized, then measure its amperage draw. It will be lower than normal. Next, monitor the compressor's suction and discharge pressures. Neither the suction nor the discharge pressure will change dramatically. There may be a very slight change in pressure, but the suction pressure will stay very high and the discharge will stay low.

To determine whether a compressor is pumping to its rated capacity is not quite as simple. A technician must measure the compressor's actual amperage draw and compare this to the amperage draw as stated by the manufacturer. The amperage should be within ± 5 percent of the manufacturer's stated value. If it is drawing less than 5 percent of its rated amperage draw, it is not pumping to its rated capacity.

Compressors can fail to start as a result of either an electrical defect or a mechanical defect. Mechanically, one or more of the pistons within the compressor can become locked and fail to move. The compressor will attempt to start, but since the pistons will not move, the compressor draws high amperage, causing it to shut down on overload.

There are three major electrical defects that will cause a compressor not to operate. One possibility is the motor windings of the compressor are open, shorted, or grounded. Another possibility is that the starting relay or capacitor as shown in Figure 88-4 are defective. The third possibility is that the incorrect voltage is applied to a compressor.

Figure 88-4 Starting components (relay and capacitor) used on a single-phase compressor.

Figure 88-5 Measuring the resistance of a compressor.

To check the condition of the compressor's motor windings, a technician will need to measure the resistance of the windings using a standard ohmmeter, as shown in Figure 88-5. For single-phase compressors, measure the resistance value of both the run and start windings and measure the resistance of each winding to ground. For three-phase compressors, each of the three windings will need to be checked. If the correct resistance value is measured across its windings, as shown in Figure 88-6, and an OL is measured from the windings to ground, as shown in Figure 88-7, then the windings are satisfactory.

TECH TIP

The voltage applied to a three-phase motor must be balanced, meaning the applied voltage to each leg must be relatively the same. The applied voltage must not deviate more than 2 percent from the average supplied voltage. A voltage imbalance of greater than 2 percent will cause the windings within a motor to generate heat beyond safe levels, leading to premature motor failure.

Figure 88-6 Measuring the resistance of a good compressor.

Figure 88-7 Measuring the resistance of an open winding on a compressor.

There is a common scenario in which a compressor may appear to be defective when in fact it is not. A compressor with an internal overload that has overheated will shut down and will not restart until the compressor has cooled. If a technician performs a resistance check on the compressor, the first step will be to measure the resistance from common to run and common to start, which will be OL. The technician may interpret this to be an open winding in the compressor. However, if the compressor is allowed to cool down and the internal overload to reset, the technician may find that the compressor will start normally and will not need to be replaced. The reason why the compressor overheated will need to be identified and resolved.

A compressor with a defective run capacitor will draw higher than normal amperage and cycle off on its overload or not start at all. If a compressor incorporates a start relay and a start capacitor and either is defective, the compressor will most likely not start.

Incorrect voltage applied to a compressor may cause it to run for a brief time then cycle off on its overload or not start at all. A service technician must first verify the correct voltage for the compressor and then measure to see what actual voltage is applied. Most compressors are rated with a tolerance of ± 10 percent. If the applied voltage is outside these limits or those stated by the manufacturer, it must be corrected before the compressor can be properly diagnosed.

Using a Compressor Analyzer

One option when troubleshooting a single-phase hermetic compressor that does not start is to use a compressor analyzer. This tool will allow a technician to start a single-phase compressor directly without using any of the system's starting components. It will connect directly to the terminals of the compressor and use its own starting components to start the compressor. This will allow a technician to determine if the fault is with the compressor or with its starting components. Some compressor analyzers will also allow a technician to check the integrity of the compressor's windings and momentarily reverse the rotation of the rotor within the compressor.

Compressor Amperage Ratings

Compressor manufacturers will publish a rating chart for each compressor they manufacture. These charts are most often in a table, or in graphic format. The compressor chart will list the correct amperage draw for the compressor under various operating conditions. To use the chart, a technician must know the evaporating temperature, condensing temperature, and voltage applied to the compressor. By using the compressor chart, a technician can determine the correct amperage draw for the compressor and use that information to accurately troubleshoot the compressor and the system.

Obtaining these charts can be time-consuming, but the extra time involved in finding the correct amperage is worthwhile. With the use of the Internet, this information is now easier to obtain.

Most manufacturers will stamp the rated load amperage (RLA) on their compressors. However, a service technician cannot use this value to determine the correct operating amperage. RLA is a mathematical calculation required to meet Underwriters Laboratories (UL) approval. The compressor manufacturer must run a series of tests to determine the maximum continuous amperage before the overload trips. Once that has been determined, UL divides the MCC by 1.56 to determine the RLA. The primary value of the RLA is to determine at what amperage draw the compressor overload will trip. This will be used to determine the fuse/circuit breaker size and the wire size. The RLA is not a reliable indicator of what the compressor amp draw should be. The amp draw of a properly operating compressor can be considerably lower than its RLA rating. A better indicator would be current ratings for specific operating conditions.

When measuring the amperage draw of a compressor, make sure to read only the amperage drawn by the compressor. Choose a location on the wiring diagram that will isolate the compressor from any other loads, such as the condensing fan motor. It is important to measure amperage draw of the *compressor only* when trying to determine if it is operating properly.

Compressor Overheating

A major cause of premature compressor failure is the compressor operating at elevated temperatures. Temperatures in the compressor head and cylinder become so hot that the oil thins and loses its ability to lubricate. This may cause rings, pistons, and cylinders to wear, resulting in blow-by, leaking valves, and metal debris in the oil.

Cylinder temperatures exceeding 300°F will begin the breakdown of the oil, and at 350°F it will vaporize. When servicing a system, it is a good practice to check the operating temperature of the cylinders. To measure the cylinder temperature of a compressor, place a temperature gauge no more than 6 in out on the discharge line from the compressor and add 50°F–75°F to the measured pipe temperature. This will give an approximate temperature of the cylinders. For most applications, the discharge line temperature should be 225°F and below. A temperature of 250°F indicates a dangerous level. A temperature of 275°F and above indicates certain failure of the compressor.

Figure 88-8 This compressor has been changed out four times.

Preventing Repeat Compressor Failure

When a compressor fails, its troubleshooting and replacement are relatively simple and common procedures. However, discovering *why* the original compressor failed may not be as simple. But it is extremely important for a technician to find this answer. Replacing the defective compressor without finding the cause will most likely result in the replacement compressor failing as well. Replacing the compressor a second, third, or fourth time is not advantageous to the service contractor or to the customer. It can cause the service contractor to lose money and quite possibly the customer. Figure 88-8 shows a compressor that has been changed four times within an 18-month period.

In most cases, upon original inspection of a defective compressor it is difficult to determine what caused the compressor to fail. The compressor is not normally running and the system is not refrigerating. After replacing the compressor, the technician should spend time discovering why the original compressor failed. With a detailed inspection, the technician should be able to find the cause. The inspection should include checking the operating suction and discharge pressures, the amount of superheat at the compressor inlet (Figure 88-9), the return-gas temperature,

Figure 88-9 Checking the superheat at the inlet of a compressor.

the discharge-gas temperature, the amperage draw, and the applied voltage to the compressor. By comparing these readings to the manufacturer's specifications, the cause should be identifiable.

Some typical causes of a compressor failure are liquid returning to the compressor, high return-gas temperature, high discharge-gas temperature, or incorrectly applied voltage to the compressor. Most of these causes can be found once the compressor is up and running.

There are times, however, when the apparent cause cannot be found upon start-up. The technician should monitor the system's operation for a period of time to find the cause. The problem may develop after the system has been running for some time—for example, during or after a defrost cycle—or as the result of an iced evaporator coil.

Another helpful troubleshooting step is to disassemble the defective compressor and examine the valve plates, pistons, crankshaft, bearing surfaces, and windings. Although this is time-consuming, it can significantly help to identify or confirm the cause of the original failure. Unit 15 has more details on specific types of compressor failures and how to recognize them.

88.5 STARTING RELAYS

Many commercial refrigeration systems use single-phase compressors. Single-phase compressor motors have a run winding and a start winding. The main purpose of the start winding is to add an additional electrical circuit that is out of phase with the main circuit. The phase displacement between the start and run windings creates the torque required to start the compressor. An external relay is used to remove the starting components from the circuit after the compressor starts. Depending upon the type of compressor motor used, the electrical components that must be dropped out can be just the start winding, just a start capacitor, or the start winding and start capacitor. Split-phase motors drop out the start winding, capacitor start motors drop out both the start capacitor and the start winding, and capacitor start-run motors drop out just the start capacitor.

There are three types of starting relays used on single-phase compressors:

- Current relay (Figure 88-10)
- PTC relay (Figure 88-11)
- Potential relay (Figure 88-12)

Current Relays

Current relays are unique. They operate based on the amp draw through the coil, not applied voltage. Current relay coils are wired in series with the run winding of the motor they are controlling (Figure 88-13). The normally open contacts of the current relay are wired in series with the start winding (Figure 88-13). When the compressor is first energized, there is a circuit through the current relay coil to the run winding but not to the start winding, because the current relay contacts are normally open. The compressor cannot start and draws locked rotor amps. The high amp draw causes the normally open contacts to close, energizing the starting winding. The compressor starts, the amp

Figure 88-10 Current relay.

Figure 88-11 PTC relay.

Figure 88-12 Potential relays: RBM on left, GE on right.

Figure 88-13 Current relay wiring diagram.

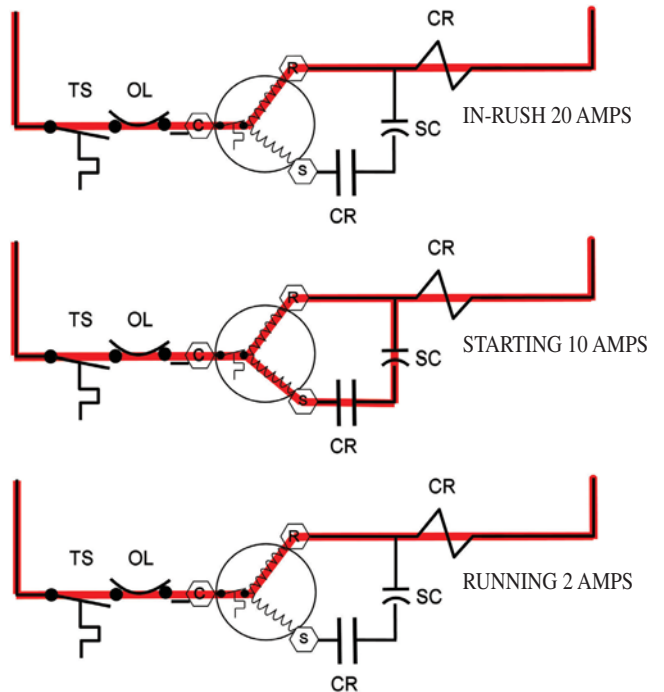

Figure 88-14 Diagram showing current relay operation.

draw drops, and the current relay contacts open back up. Thus, the contacts start out open, they close during start-up, and they open again during operation (Figure 88-14). Current relays must be carefully matched to the motors they control since the motor operating characteristics determine how the relay reacts.

Current relays are only used on fractional-horsepower compressors because the compressor locked rotor current must pass through the relay coil. Current relays typically plug directly onto the compressor terminals for small compressors (less than 1/4 hp) (Figure 88-15). Current relays for larger compressors (1/2 hp) are mounted separately (Figure 88-16).

PTC Relays

PTC stands for "positive temperature coefficient" thermistor. The "contacts" are actually a resistor that increases in resistance as it heats up. Unlike actual contacts, the thermistor never really opens. Its resistance just gets so high that the amount of current passing through is negligible. PTC relays are now more common on small compressors

Figure 88-15 The current relay plugs directly onto the compressor terminals on small compressors.

Figure 88-16 The current relay is mounted away from the terminals on larger compressors.

than current relays. Like small current relays, PTC relays typically mount right to the compressor terminals (Figure 88-17). PTC relays are wired in series with the start winding (Figure 88-18).

Potential Relays

Potential relays are used for larger single-phase motors. They have a coil that wires in parallel to the compressor start winding and a normally closed set of contacts that is wired in series with the start winding (Figure 88-19). Potential relays operate at a voltage that is higher than the line voltage supplied to the compressor because the back electromotive force (back emf) produced across the start winding is usually higher than the line voltage. The back emf increases as the compressor speed increases. The potential relay is calibrated to open its contacts when the compressor reaches approximately 75 percent of its full speed.

Figure 88-17 PTC relays mount right to the compressor terminals.

Figure 88-18 Diagram of a PTC starting relay.

Figure 88-19 Diagram of a potential relay.

TECH TIP

Counter electromotive force, or back emf, is a voltage produced in AC magnetic devices as a result of the changing current flow through the device. It is called counter, or back electromotive force because it opposes the original voltage. Back emf is the primary opposition to current flow in most AC magnetic devices, including motors. The faster the motor turns, the higher the generated back emf.

Figure 88-20 When checking the amp draw through the start capacitor, you should see a reading when the compressor starts, then it should quickly drop to 0.

88.5 TESTING THE STARTING CIRCUIT

The best way to test any of these starting circuits is to check the amp draw through the starting circuit. It should spike when the compressor starts and then drop to zero after the compressor is started. This all happens very quickly. Figure 88-20 illustrates how this works. If any of the starting components are open, the amp reading on the starting circuit will be zero. The amp draw on the run winding will likely be locked rotor amps because the compressor will not start. In this case you need to check the starting relay, capacitor, and start winding to see if any are open. If the amp draw spikes, the compressor starts, but the amp draw does not drop to zero, then the starting relay is not dropping out. This usually indicates a bad starting relay. However, this can also be caused by a compressor that starts but does not get up to full speed because of mechanical or refrigeration problems.

88.6 TESTING START RELAYS

Many times a technician will need to determine if the capacitor or starting relay used on a compressor is the cause of the compressor not starting or operating properly. To properly inspect these components, they must be electrically removed from the system. Then, using a standard multimeter or capacitance meter, the component can be tested to see if it is electrically acceptable.

Current Relay

To test a current relay using an ohmmeter, first remove the relay from the circuit. Hold the relay in the upright position and check the resistance between the L and M terminals of

Figure 88-21 The current relay coil on top is good; the one on the bottom is bad.

the relay. If the ohmmeter reads approximately $0.1\ \Omega$, the coil of the relay is good. If the meter reads an infinite reading (OL), the coil is open and the relay needs to be replaced (Figure 88-21).

Next, place the ohmmeter leads on the M and S terminals of the relay. If the ohmmeter reads an OL, the contacts are open—as they should be. If the meter reads 0 or a measurable resistance, the contacts are stuck closed. The relay will need to be replaced (Figure 88-22). Next, try turning the relay upside down and shaking it. The contacts should be

Figure 88-22 The contacts should be open (OL) with relay upright and closed (0) with the relay upside down.

Figure 88-23 The PTC relay on the top is good; the relay on the bottom is bad.

closed, showing a low or zero resistance on the ohmmeter (Figure 88-22). However, turning the relay upside down will not close the contacts on all current relays.

PTC Relay

To check a PTC relay, check the resistance through the relay. The relay should have a low resistance when it is cold. Make sure the relay is cool. If it is still hot, the thermistor will still have a high resistance. If you read a high resistance or infinity with a cold PTC relay, the relay is bad (Figure 88-23).

Potential Relay

Remove the relay from the circuit and read the resistance between the 2 and 5 terminals of the relay. If the ohmmeter reads a high resistance (approximately 6,000–14,000 Ω) the coil is good. If the coil reads OL, it is open and the relay needs to be replaced. Next, read the resistance between the 1 and 2 terminals on the relay. If the ohmmeter reads zero, the contacts are closed—as they should be. If the ohmmeter reads a high resistance or an OL, the contacts are defective and the relay needs to be replaced.

88.7 TESTING CAPACITORS

Capacitors will normally fail open or shorted. They can be tested with a multimeter or a capacitor tester. Normally a visual inspection of a capacitor will indicate a defect. On run capacitors, any sign of bulging of its body is a sign of a defect (Figure 88-24). Start capacitors will have a rubber membrane located on the top portion of the capacitor. If this membrane blows out, it is a sign of a defect (Figure 88-25).

Figure 88-24 The bulge in this run capacitor indicates that it is bad.

SAFETY TIP

Capacitors have the ability to store an electrical charge. Because of this, a technician should always discharge a capacitor before handling or checking it. A capacitor can be safely discharged using a 20,000 Ω , 5 W resistor with an insulated pair of pliers. Some start capacitors have a bleed resistor across the terminals designed to discharge the capacitor. It is still a good practice to discharge these capacitors with your own resistor. The resistor on the capacitor may be electrically open and may not have discharged the capacitor.

Figure 88-25 The ruptured membrane on the top of the capacitor and the white residue on the bottom capacitor indicate that they have been overheated and are bad.

Testing with an Analog Ohm Meter

The following procedure can be used to test a capacitor using an analog ohmmeter:

1. Remove the capacitor from the circuit.
2. Discharge the capacitor with a bleed resistor or a voltmeter.
3. Set an ohmmeter to its highest scale. Zero the ohmmeter.
4. Place the ohmmeter leads on the capacitor terminals.
5. Watch for one of the following indications of the conditions of the capacitor:
 - a. Good—needle will swing toward 0 and then slowly return to infinity.
 - b. Shorted—needle will swing toward 0 and remain there.
 - c. Open—needle will stay at infinity.
6. Make a second test by reversing the leads of the ohmmeter.
7. For run capacitors with metal cases, place one of the ohmmeter leads on a terminal of the capacitor and one lead on the body. If the ohmmeter reads a resistance, the capacitor is grounded and needs to be replaced. Next, test the other lead of the capacitor.

Testing with a Digital Multimeter or Capacitor Analyzer

Most digital multimeters intended for HVACR use have a scale specifically for testing capacitors (Figure 88-26). These meters typically will discharge the capacitor and then display its capacity in microfarads. To test capacitors using a capacitance meter, simply discharge the capacitor and place the meter leads across the terminals of the capacitor. If the capacitor is OK, the actual capacitance (within 10 percent of its original value) will be displayed on the

Figure 88-26 Capacitor test setting on digital multimeter.

screen. If the capacitor is shorted, then the display will indicate a value close to zero. If the capacitor is open, it will normally show an OL on its display.

SERVICE TIP

The capacitor testing function on many multimeters will not read correctly if the capacitor has a bleed resistor. The bleed resistor must be removed from one side of the capacitor to use the capacitor test function on these meters.

88.8 TROUBLESHOOTING EVAPORATOR PROBLEMS

An evaporator is a heat exchanger used to absorb heat from the refrigerated product. Heat is transferred from the product through the tubing and fins of the evaporator to the refrigerant. If the evaporator's surface becomes insulated as the result of either being dirty or covered with ice, the amount of heat transfer will be dramatically reduced.

Ice buildup can occur when the heat load on the evaporator is reduced. As a result, the temperature of the evaporator drops and an excessive amount of frost and ice accumulates on its surface. For example, a blower-type evaporator needs the correct amount of airflow across its surface. If this airflow is restricted as a result of one or more defective fan motors, the surface of the evaporator will develop an excessive amount of ice and the system will not be able to absorb enough heat from the product to maintain the desired case temperature.

With an evaporator temperature below 32°F, frost will naturally develop on the surface of the evaporator even if the correct heat load is applied. The design of the refrigeration system must incorporate some means of defrosting the evaporator on a regular basis to prevent an excessive amount of frost from developing on the surface of the evaporator. Medium-temperature refrigeration systems will use the case air to defrost the evaporator. When the refrigeration system shuts down, the evaporator fan continues to operate and will continue to draw case air across the evaporator to melt any frost that has accumulated. However, with low-temperature systems the case temperature is well below 32°F and therefore the case air cannot be used to defrost the evaporator. Low-temperature systems require some type of supplemental heat to defrost the evaporator surface.

Troubleshooting Defrost Problems on Freezers

A frozen evaporator coil is a common problem found when troubleshooting freezers. Although there are several possible causes for this problem, one common cause is the defrost system. The system is not properly defrosting the evaporator's coil on a regular basis. To effectively troubleshoot this problem, a technician must understand the design and operation of the defrost systems typically used.

Defrost system problems fall into two categories. The system may be over-defrosted or under-defrosted. Over-defrosting is when the defrost heater stays energized too long, causing the box temperature to rise too high during

defrost. The product may begin to melt and then refreeze. This problem can be identified by monitoring the box temperature during defrost or by examining the product in the case. Ice crystals forming on frozen product may be an indication of melting and refreezing. Over-defrosting is normally caused by a malfunction in the defrost cycle termination. On time defrost systems, either the defrost time is set too long or the time clock is defective. On time-pressure systems, either the terminating pressure control is set too high, the pressure control is defective, or the solenoid coil in the defrost timer is incorrectly wired or defective. On time-temperature systems, either the temperature control is set too high, the control is defective, or the solenoid in the defrost timer is defective.

Systems that are under-defrosting will result in a frozen evaporator. The frost that normally develops on the evaporator coil will continue to build until the entire surface of the evaporator is iced over. This can be caused by a defective or incorrectly set time clock that does not initiate a defrost cycle. It can also be caused by an open heater element or a defective defrost termination switch that continually terminates defrost on each initiation of a new cycle.

When an evaporator ices over, a technician will need to defrost the coil. Sometimes this can be done by manually initiating a defrost cycle. This can be done on a mechanical defrost timer by rotating the inner knob counter-clockwise (Figure 88-27). Many times, however, this cannot be done. The technician will have to manually defrost the coil. Extreme care must be taken when doing this. Do not use any sharp objects to chip away ice from the coil—this could easily puncture the coil and cause a refrigerant leak to develop in the evaporator. Using water is the best method but is not always practical, since the water will need to be drained away. If water cannot be used easily, a heat gun usually works well. Defrosting a coil manually is time-consuming. Do not rush this procedure, as making a careless mistake can be costly.

Figure 88-27 To manually put this unit in defrost, turn the dial until one of the initiation pins reaches the arrow and the points click.

88.9 TROUBLESHOOTING CONDENSER PROBLEMS

A condenser is a heat-exchange device used to reject heat energy from the refrigerant to its cooling medium. Heat energy from the refrigerant is rejected through the tubing and fins of the condenser and absorbed by the condensing medium. There are several problems that can occur that can impede this process. If the condenser's surface becomes insulated as a result of being dirty, it will reduce the ability of the cooling medium to absorb heat from the refrigerant. This will cause the discharge pressure of the system to rise beyond its normal operating range and cause the system to malfunction.

Determining Discharge Pressures

When troubleshooting commercial refrigeration systems, many times it is necessary to measure the discharge pressure of a system and determine if the pressure is normal, higher than normal, or lower than normal. To make this determination, the correct operating discharge pressure must be known. For systems utilizing an air-cooled condenser, this can be determined by measuring the system's suction pressure and the temperature of the air entering the condenser.

Below are the general procedures for determining the correct operating discharge pressure of a commercial refrigeration system utilizing an air-cooled condenser.

- Step 1.** Measure the dry-bulb temperature of the air entering the condenser. (We will refer to this as the EAT—entering air temperature.)
- Step 2.** Measure the system's operating suction pressure.
- Step 3.** Using a pressure/temperature (PT) chart, convert the suction pressure to its equivalent saturation temperature.
- Step 4.** Determine the system's application for this procedure: low temperature, medium temperature, or high temperature. A low-temperature system is one that operates at an evaporating temperature of -40°F to $+10^{\circ}\text{F}$. A medium-temperature system is one that operates at an evaporating temperature of between -10°F and $+30^{\circ}\text{F}$. A high-temperature system is one that operates at an evaporating temperature of between $+20^{\circ}\text{F}$ and $+55^{\circ}\text{F}$.
- Step 5.** Using the chart in Table 88-1, determine the appropriate temperature rise (TR). The TR is the difference between the EAT and the condensing temperature of the refrigerant in the condenser.
- Step 6.** The condensing temperature (CT) can then be determined by adding the EAT and the TR. $\text{CT} = \text{EAT} + \text{TR}$.
- Step 7.** Once the CT is known, its equivalent saturation pressure can be determined using a PT chart. This will be the correct operating discharge pressure of the system.

For example, suppose we are working on a walk-in cooler using R-134a refrigerant with an operating suction pressure of 18.4 psig and 76°F air temperature entering the condenser.

- Step 1.** The EAT in our example is 76°F .
- Step 2.** The system's operating suction pressure is 18.4 psig.
- Step 3.** Using a PT, chart we convert our suction pressure of 18.4 psig to a saturation temperature of 20°F .

Table 88-1 Condenser Temperature Rise for Different Evaporator Temperatures

Condenser Temp Rise (TR) °F	Condenser Temperature Rise (TR) °F		
	Evaporator Temperature		
	Low Temp	Medium Temp	High Temp
20	-25	0	—
23	-20	5	25
26	-15	10	30
29	-10	15	35
32	-5	20	40
35	0	25	45

Step 4. We determine the system's application to be medium temperature.

Step 5. Using Table 88-1, we determine the appropriate TR to be 32°F.

Step 6. The CT of our system will be 108°F ($108^{\circ}\text{F} = 76^{\circ}\text{F} + 32^{\circ}\text{F}$).

Step 7. Again using a PT chart, we can conclude that our operating discharge pressure should be 142.8 psig.

Using this procedure should help determine if the discharge pressure of a commercial refrigeration system is normal, higher than normal, or lower than normal.

Checking for Noncondensable Gases

The only fluids circulating within a refrigeration system should be refrigerant and oil. Any other fluids contained in the system may reduce its capacity and cause harm to the system. One common contaminant that can enter a system is air. Air contains nitrogen and oxygen, both of which are harmful to a refrigeration system. When a system has been open to the atmosphere for servicing, it must be completely evacuated to remove the unwanted air before adding refrigerant.

One problem when air is contained in a system is that it will become trapped in the condenser and will not condense. It will take up space, causing less surface area for the refrigerant to condense. This will cause the high-side pressure to elevate, causing further problems, such as higher discharge temperatures and reduced system capacity.

Occasionally a technician may need to check whether noncondensables such as air are contained in a system. Use the following procedure to determine this in a refrigeration system with an air-cooled condenser.

- Determine the type of refrigerant in the system.
- Electrically disable the compressor and allow the condenser fan to operate.
- Attach a temperature probe to both the discharge line and liquid line, shown as in Figure 88-28.
- Place a third temperature probe to measure the temperature of the air entering the condenser.
- Connect a pressure gauge to the system to measure the pressure of the refrigerant in the condenser.

Figure 88-28 When checking for air in a refrigeration system, take temperatures at three locations: the discharge line at the inlet of the condenser, the liquid line at the outlet of the condenser, and the temperature of the air entering the condenser.

- When all three temperature probes (discharge line, liquid line, and air entering the condenser) read the same temperature, record the pressure of the refrigerant in the condenser.
- Using a PT chart, convert the measured pressure to its saturation temperature.
- The converted temperature should be within a few degrees of the measured discharge, liquid, and air entering temperatures.
- If the converted temperature is higher than the measured temperatures by more than a few degrees, there are noncondensables in the system that need to be removed.

88.10 TROUBLESHOOTING METERING DEVICES

Metering devices are refrigerant flow-control devices that feed the proper amount of refrigerant into an evaporator. If a metering device is defective it will either feed too much or too little refrigerant into the evaporator. To determine

if too much or too little is being fed into an evaporator, a technician must measure the superheat level of the refrigerant leaving the evaporator. If the superheat value is higher than recommended by the equipment manufacturer, too little refrigerant is being fed into the evaporator. If the superheat value is lower than recommended by the equipment manufacturer, too much refrigerant is being fed into the evaporator. Both of these conditions could be the result of a defective metering device. However, before deciding that the problem is the metering device, make sure all other possible causes are investigated and eliminated. Many times it may appear the metering device is not functioning properly but another system problem is the actual cause.

88.11 TROUBLESHOOTING THERMOSTATIC EXPANSION VALVES

A thermostatic expansion valve (TEV) is designed to maintain a specific amount of superheat at the outlet of the evaporator. If the superheat value is too high or too low at the outlet of the evaporator, the cause may be the TEV. However, as mentioned previously, make sure all other possible causes are investigated first before determining that it is the TEV.

If the TEV is the cause of the system problem, try adjusting the valve first. To increase the superheat setting of the valve, turn the adjustment stem clockwise. To decrease the superheat setting of the valve, turn the adjustment stem counterclockwise. If adjusting the valve does not resolve the problem, then the valve is defective and will need to be replaced.

Some common causes of an evaporator with a low superheat and a high suction pressure are as follows:

- Oversized valve
- TEV seat is leaking
- Low superheat adjustment
- Sensing bulb making poor thermal contact
- Wrong thermostatic charge
- Incorrectly located external equalizer
- Restricted or capped external equalizer

Some common causes of an evaporator with a high superheat and a low suction pressure are as follows:

- Restricted filter drier
- Restricted TEV inlet screen
- Undercharged system
- Undersized valve
- High superheat adjustment
- Gas charge condensation
- Dead thermostatic element charge
- Wrong thermostatic charge
- Evaporator pressure drop—no external equalizer
- External equalizer location

88.12 TROUBLESHOOTING CAPILLARY TUBES

A capillary tube is simply a section of tubing with a very small inside diameter. A problem that does occur with these metering devices is that they can become restricted.

Either they can be totally restricted where no refrigerant will pass through or partially restricted where some refrigerant will pass through but not enough to properly feed the evaporator. A system with a restricted capillary tube will have a low suction pressure and a discharge pressure that is slightly lower than normal.

Occasionally it may be difficult to determine the difference between a system with a low refrigerant charge, a restricted capillary tube, or a restricted filter drier (or strainer). A system with a low refrigerant charge will have both a low suction pressure and a low discharge pressure. A system with a restricted capillary tube will have a low suction pressure and a discharge pressure that is lower than normal but not quite as low as a system with a low refrigerant charge. It may be difficult to determine the difference between a low discharge pressure and a slightly lower than normal discharge pressure. One method is to recover the refrigerant from the system, evacuate the system, and then recharge with the correct weighed amount of refrigerant. If the system operates properly, the problem was a low refrigerant charge and the system leak will need to be found and repaired. If weighing in the charge does not resolve the problem, then the capillary tube or the filter drier is restricted. Repeat the process, but now replace the filter drier. If the system operates properly, the filter-drier was the cause of the problem. If the problem remains, the cause is a restricted capillary tube.

88.13 USING A SHORT REFRIGERANT GAUGE

Small-capacity refrigeration systems hold relatively small amounts of refrigerant. When troubleshooting these systems, avoid installing a gauge manifold to read the system pressures when possible. The small amount of refrigerant released from the process of installing and removing refrigeration hoses may cause a system problem. Enough refrigerant could be lost to cause the system to operate with a low refrigerant charge. This is especially true if 6-ft hoses are used or if a gauge manifold set is installed on and off several times.

If a technician needs to read the system's pressure, use a short gauge setup (Figure 88-29). This will diminish the amount of refrigerant released while reading the system's pressures.

88.14 REFRIGERANT LEAK DETECTION

Loss of refrigerant from a system due to a leak is a very common service call. This problem is normally quite simple to diagnose, but locating the source of the leak can be difficult. There are several methods of finding leaks, and each has its own advantages and disadvantages. Some methods may work well to locate a leak on one system and not as well on another. A technician should be able to use more than one leak-detection method. If one method is not working well, an alternate one can be tried. Also, many times it is beneficial for a technician to employ two methods while searching for a leak: one to locate the area of the suspected leak and the other to pinpoint its location.

Figure 88-29 Use a short refrigeration gauge on systems containing small amounts of refrigerant.

Below are various ways to search for a refrigerant leak:

- **Visual inspection.** As refrigerant leaks from a system, so does a portion of the refrigeration oil. The oil will normally stain the area surrounding the location. An easy way to search for a leak is to visually inspect the lines and fittings of the system for signs of oil. Although this may not pinpoint the location, it gives a technician the general area where the leak is located. This method works well for those leaks where a technician can visually inspect all of the piping easily. This is not always possible—many times it is very difficult, or even impossible, to visually inspect all of the areas of a system.
- **Soap bubbles.** Using an approved soapy solution (Figure 88-30) is a very common method to locate leaks. Simply saturate the suspected area with the soapy solution. If a leak is present, the solution will bubble. This method works well if the area of the leak is known and if the system is adequately pressurized. This method also works well in conjunction with the other methods used to verify the location of a leak. It is normally best to use a soapy solution purchased from a supply house, but some technicians make their own solution. Homemade solutions work well as long as they do not corrode or freeze onto the tubing or fittings.
- **Electronic leak detectors.** Electronic leak detectors (Figure 88-31) are very common today. Most currently produced electronic leak detectors will do an adequate job of locating leaks. A technician should always verify the operation of the electronic leak detector before relying on it. The sensors on most detectors will need to be changed after a period of usage. By testing the operation of these leak detectors, a technician can be assured that time is not being wasted searching for a leak with a faulty detector.
- **Refrigerant dyes.** Refrigerant leaks can be identified by injecting a dye into the system. A refrigerant dye kit is shown in Figure 88-32. The dye mixes with the refrigerant oil, and the point where this mixture leaks from the system will become stained with dye. A technician can then easily locate the leak by looking for the stained area. Two basic types of dyes used are red dye and fluorescent dye.

Figure 88-30 Soap bubble solution used to identify refrigerant leaks. (Courtesy Highside Chemicals, Inc.)

Figure 88-31 An electronic leak detector used to search for refrigerant leaks.

- **Ultrasonic leak detectors.** As refrigerant is escaping from a system, it will generate a sound at a higher than normal frequency. An ultrasonic leak detector (Figure 88-33), can be used to pick up these sound waves. This method works well as long as there are no other sources within the system area that produce sound waves at the same frequency.

SAFETY TIP

It is a common practice for a technician to warm a refrigerant cylinder while adding refrigerant to keep the vapor pressure within the cylinder high enough to allow the refrigerant to efficiently transfer from the cylinder to the system. The best method for warming a refrigerant cylinder is to place it in a bucket of warm water. Never use a torch or an open flame to warm a refrigerant cylinder. A water temperature of approximately 90°F is ideal. Never use water at a temperature higher than 125°F as it may overpressurize the refrigerant cylinder.

Figure 88-32 A refrigerant dye kit (HVAC fluorescent leak detection system).

Figure 88-33 An ultrasonic leak detector.

One basic rule a technician *must* follow while searching for a leak is *have patience*. At times this process can be very tedious, and a technician must have patience and be diligent; otherwise it can be a very frustrating procedure.

UNIT 88—SUMMARY

Patience is a requirement when troubleshooting refrigeration systems. A good service practice is to spend some time speaking to the customer before looking at the system and then conduct a visual inspection of the system to look for any obvious system problems.

Electrical troubleshooting can be divided into two types: (1) electrically diagnosing controls (switches, relays, and contactors) and (2) electrically diagnosing loads (coils, fan motors, and compressors). A voltmeter measures whether an electrical potential (voltage) is present at a switch or a load. An ammeter is used to measure how much current a load is consuming. An ohmmeter measures the resistance of an electrical component. Capacitors will normally fail open or shorted. This can be tested with an ohmmeter or a capacitor tester.

Compressor problems can be divided into two groups: mechanical or electrical. Mechanical defects are problems that affect the operation of the mechanical pump inside the compressor, such as blown valve plates, a broken crankshaft, or worn pistons. Compressor manufacturers will publish a rating chart for each compressor they manufacture. The compressor chart will list the correct amperage draw for the compressor under its various operating conditions. A major cause of premature compressor failure is the compressor operating at elevated temperatures.

A technician manually defrosting an evaporator must use extreme care. Do not use any sharp objects to chip away ice from the coil, as this could easily puncture the coil and cause a refrigerant leak to develop in the evaporator.

A thermostatic expansion valve (TEV) is designed to maintain a specific amount of superheat at the outlet of the evaporator. If the superheat value is too high or too low at the outlet of the evaporator, the cause may be the TEV. However, make sure all other possible causes are investigated first before determining that it is the TEV.

Small-capacity refrigeration systems hold relatively small amounts of refrigerant. When troubleshooting these systems, avoid installing a gauge manifold to read the system pressures when possible.

WORK ORDERS

Service Ticket 8801

Customer Complaint: Compressor Not Running

Equipment Type: Walk-in Cooler

A technician is called out to service a walk-in cooler using R-134a refrigerant, an air-cooled condenser, TEV metering device, and a constant cut-in temperature control and operating at a case temperature of 60°F.

When the technician arrives on the job, the condenser and evaporator fans are running, and the compressor is not running and cycles on overload when voltage is applied to the compressor. After further investigation, the technician observes the following conditions:

- The condenser coil is clean.
- The low pressure is set for a cut-in of 20 psig and a differential of 15 psig.
- The high-pressure control is set for a cut-out pressure of 250 psig.
- 232 V are measured across the common and run terminals of the compressor.
- The following resistances are measured across the terminals of the compressor.
- Common to run—3 Ω

- Common to start—10 Ω
- Run to start—13 Ω
- The run capacitor reads a capacitance of 35 mfd.
- The start capacitor reads a capacitance of 198 mfd.
- A resistance reading of 7,800 Ω is measured across terminals 2 and 5 of the potential relay.
- A resistance reading of infinity is measured across terminals 1 and 2 of the potential relay.

The technician decides to replace the potential relay.

Service Ticket 8802

Customer Complaint: Freezer Not Cooling Properly

Equipment Type: Walk-in Freezer

A technician is called out to service an 8 ft \times 10 ft \times 7ft, 6-in walk-in freezer that is operating at a 20°F case temperature. The system has an air-cooled condensing unit with a semihermetic compressor located indoors on top of the freezer. The system uses R-404A refrigerant and an externally equalized TEV. The system is controlled by a temperature controller and a pump-down solenoid. The system is using an electric defrost heater and a time/temperature defrost method.

When the technician arrives on the job, the compressor, condenser, and evaporator fans are running. After further investigation, the following conditions are observed:

- Ambient temperature is 75°F.
- The condenser and evaporator coils are relatively clean and there is no obstruction to airflow through them.
- Operating suction pressure is 16 psig.
- Operating discharge pressure is 240 psig.
- The suction line temperature is 20°F at the outlet of the evaporator.
- The liquid line temperature is 85°F at the outlet of the condenser.
- The sight glass is clear.
- There is no temperature drop across the liquid-line filter drier.

Based on these observations, the technician determines to replace the TEV.

Service Ticket 8803

Customer Complaint: Reach-in Cooler Not Cooling Properly

Equipment Type: Reach-in Cooler

A technician is called out to service a reach-in cooler using R-134a refrigerant, an air-cooled condenser, capillary-tube metering device, and constant cut-in temperature control and operating at a case temperature of 60°F.

When the technician arrives on the job, the condenser and evaporator fans are running, but the compressor is hot and not running. After further investigation, the technician observes the following conditions:

- The evaporator coil is clean.
- The condenser coil is relatively clean.

- The temperature control is set on its #5 position.
- 115 V is measured at the C and R terminals of the compressor.
- With the voltage removed and the relay disconnected from the compressor, an infinite resistance (OL) is measured between the C and R terminals of the compressor.
- With the voltage removed and the relay disconnected from the compressor, 12 Ω is measured between the S and R terminals of the compressor.
- With the start capacitor removed from the system, 189 mfd is measured across its terminals.
- With the current coil relay removed from the system, approximately 1 Ω is measured across its coil.
- With the current coil relay removed from the system, 0 Ω is measured across its contacts.

The technician then decides to replace the current coil relay.

UNIT 88—REVIEW QUESTIONS

1. What are the two areas into which electrical troubleshooting can be divided?
2. What are the three major tools commonly used to troubleshoot the various electrical components of a refrigeration system?
3. Which tool measures whether an electrical potential is present at a switch or a load?
4. Which tool measures how much current a load is drawing?
5. Explain the groups into which compressor problems can be divided.
6. How can a technician determine whether a compressor is not pumping to its rated capacity?
7. What are the three major electrical defects that can cause a compressor not to operate?
8. What is the maximum voltage imbalance of a three-phase compressor?
9. What does RLA stand for when stamped on a compressor?
10. At what cylinder temperature will oil break down inside a compressor?
11. What should a technician do after changing out a defective compressor?
12. Explain how to test whether a current relay is defective using an ohmmeter.
13. Explain how to test whether a potential relay is defective using an ohmmeter.
14. Explain how to test whether a capacitor is defective using an ohmmeter.
15. Explain how a technician should manually defrost a frozen evaporator coil.
16. Explain a method used to determine the correct operating discharge pressure of a commercial refrigeration system.
17. Explain a method used to determine whether noncondensables are in a refrigeration system.
18. List some common causes of an evaporator operating with a low superheat and a high suction pressure.
19. A technician should use a short refrigeration gauge on what type of refrigeration systems?
20. List some methods of searching for refrigerant leaks.

UNIT 89

Installation Techniques

OBJECTIVES

After completing this unit, you will be able to:

1. list the industry organizations that set equipment and installation standards.
2. list and describe the major phases of system installation.
3. discuss the factors affecting equipment placement.
4. discuss the procedure for selecting and sizing the power wiring, disconnect, and overcurrent protection.
5. discuss correct refrigeration piping procedures.
6. determine the correct charge for a new air-conditioning installation.

89.1 INTRODUCTION

The first step in a successful installation is reading the manufacturer's instructions. The secret to avoiding unpleasant surprises is taking some time to research what the manufacturer and all applicable national and local codes require. The time spent preparing will make the installation run smoothly and save time overall. Paradoxically, the key to speeding up is slowing down.

Proper installation is critical to every system. An 18-SEER air conditioner incorrectly installed could perform like a 10-SEER system. In most cases, a correctly installed lower-efficiency system will outperform an incorrectly installed higher-efficiency system. A good installation is the first step toward providing long equipment life, reliable operation, and energy efficiency.

89.2 STANDARDS, CODES, ORDINANCES, AND LAWS

Equipment installation instructions typically include a statement such as "All work should be performed in accordance with applicable national and local codes and standards." These regulations may apply to the design and performance of a product, its application, its installation, or safety considerations. Understanding what the rules are that you must follow is important. Standards, codes, ordinances, and laws are all essentially sets of rules.

Standards are generally not intended to be legal documents but rather a description of best practices. They are intended to inform and guide professionals. Standards are normally offered by industry groups such as ACCA, AHRI, ASHRAE, ASME, CGA, or UL.

Codes also describe how things should be done, but they generally describe the minimum acceptable installation. Codes focus heavily on safety. Codes are intended to be adopted as law. They are written by industry entities that specialize in writing code, including ICC, NFPA, and IAPMO. New code versions are published every 3 years. Although codes are intended to be legal documents, the organizations that write them are not part of the government and

have no legal authority to enforce their codes. Codes have no legal effect until a government agency adopts them.

Code names such as the National Electric Code, the International Residential Code, or the Uniform Mechanical Code sound as if they are part of national law. Despite their names, there is no federal or national code-enforcement agency. Code enforcement is done at the state or local level. When states adopt a code, they often add a few changes, or amendments, to the existing code. Application of the same basic code can vary slightly from state to state. The amended code is usually referred to in that state as the state code. For example, the Georgia State Minimum Standard Mechanical Code is the International Mechanical Code with Georgia Amendments. Local codes are usually divided into the following sections:

- Electrical
- Plumbing
- Mechanical (air conditioning and refrigeration)
- Other (such as sound control)

Local inspectors enforce these codes based on the permits issued.

89.3 STANDARDS ORGANIZATIONS

There are many different industry organizations that publish standards. For most of these organizations, writing standards is only part of what they do. Each has a different core constituency, but all of them contribute to the body of standards we use in the HVACR industry.

ACCA (Air Conditioning Contractors of America)

ACCA is a nonprofit association serving more than 60,000 professionals and 4,000 businesses in the HVACR community. ACCA works to promote professional contracting, energy efficiency, and healthy, comfortable indoor living for all Americans. They produce many publications on air-conditioning system design and installation, including Manual J, Manual D, and the Quality Installation Standard.

AHRI (Air-Conditioning Heating and Refrigeration Institute)

AHRI is an association of manufacturers of refrigeration, air conditioning, and heating equipment and allied products. Although it is a public relations and information center for industry data, one of the institute's most important functions is establishing product or application standards by which the associated members can design, rate, and apply their hardware. In some cases, the products are submitted for test and are subject to certification and are listed in nationally published directories. The intent is to provide the user with equipment that meets a recognized standard. The standards used for rating HVACR equipment are published by AHRI.

ANSI (American National Standards Institute)

ANSI was formed in 1918. The Institute oversees the creation, promulgation, and use of thousands of norms and guidelines that directly affect businesses in nearly every sector, including HVACR. The ANSI mission is to enhance both the global competitiveness of U.S. business and the U.S. quality of life by promoting and facilitating voluntary consensus standards and conformity-assessment systems and safeguarding their integrity. ANSI often strengthens the standards of HVACR organizations by adopting their standards as an ANSI standard.

ASHRAE (American Society of Heating, Refrigeration, and Air-Conditioning Engineers)

ASHRAE started in 1904 as the American Society of Refrigeration Engineers. Today its membership includes thousands of engineers and technicians from all areas of the industry. ASHRAE creates standards for system design and application. ASHRAE Standard 90, Energy Standard for Buildings, is very popular because of the increased emphasis on energy-efficiency. ASHRAE publishes a series of handbooks that have become the reference bibles of the HVACR industry. These include *Fundamentals*, *Applications*, *HVAC Systems and Equipment*, and *Refrigeration*.

ASME (American Society of Mechanical Engineers)

ASME is concerned primarily with codes and standards related to the safety aspects of pressure vessels. Around the turn of the twentieth century, steam power was being widely used. Boilers and boiler accidents were common. Thousands of people were killed each year because of boiler explosions. To counter this, the American Society of Mechanical Engineers started listing safe materials and methods of construction used in boilers in an effort to improve boiler safety. Today most mechanical codes require that all large pressure vessels holding a pressure of over 15 psig be ASME rated. This includes refrigerant receivers and high-pressure chillers as well as boilers.

ASTM International

Formerly known as the American Society for Testing and Materials, ASTM is a globally recognized leader in the development and delivery of international voluntary consensus standards. Today, some 12,000 ASTM standards are used around the world to improve product quality, enhance safety, facilitate market access and trade, and build consumer confidence. ASTM primarily tests material properties. ASTM testing is often referred to in other standards and codes. For example, the ASTM testing procedures for flame spread and smoke are referenced in standards and codes applying to duct materials.

CGA (Compressed Gas Association)

The mission of CGA is to promote the safe manufacture, transportation, storage, transfilling, and disposal of industrial and medical gases and their containers. CGA standards are often quoted in codes dealing with refrigeration cylinders, propane cylinders, acetylene cylinders, and oxygen cylinders.

CSA (Canadian Standards Association)

The CSA is a not-for-profit membership-based association serving business, industry, government, and consumers in Canada and the global marketplace. As a solutions-oriented organization, CSA works in Canada and around the world to develop standards that address real needs, such as enhancing public safety and health, advancing the quality of life, helping to preserve the environment, and facilitating trade. CSA standards applicable to HVACR include standards covering construction, electrical, mechanical systems, and occupational safety.

International Organization for Standardization (ISO)

ISO is the world's largest developer and publisher of international standards. ISO is a network of the national standards institutes of 162 countries, one member per country, with a Central Secretariat in Geneva, Switzerland, that coordinates the system. ANSI is a member body of ISO.

NEMA (National Electrical Manufacturers Association)

NEMA is the trade association of choice for the electrical manufacturing industry. Founded in 1926 and headquartered near Washington, DC, its approximately 450 member companies manufacture products used in the generation, transmission and distribution, control, and end-use of electricity. NEMA standards affecting HVACR include standards covering electric motors, motor controls, disconnect switches, and electrical protection equipment.

UL (Underwriters Laboratories)

UL is a testing and code agency that specializes in the safety aspects of electrical products, while also including an overall review of some products. The UL seal on household appliances is a familiar one, and it is also applied to the

approval of refrigeration and air-conditioning equipment. Its scope of activity has expanded into large centrifugal refrigeration machines.

UL approval for certain types of refrigeration and air-conditioning products may be mandatory by local electrical inspectors. Compliance with UL is the responsibility of the manufacturer, and the approved products are listed in a directory. Installation in accordance with the approved standards is the responsibility of the installer. Violation of these standards can cause a safety hazard as well as possibly voiding the user's insurance coverage should an accident or fire result. Installation procedures should therefore always conform to UL approval standards.

89.4 CERTIFYING AND TESTING ORGANIZATIONS

Independent laboratory testing is used to ensure that products actually meet the standards they are designed to meet. Many organizations that write standards also perform certification testing to ensure that products meet specific standards. Common certifying and testing organizations include the Air-Conditioning Heating and Refrigeration Institute (AHRI), the Canadian Standards Association (CSA), and Intertek (ETL). Codes often reference these independent industry certifications or listings. For example, electrical codes typically require appliances to be listed by a testing organization such as UL, CSA, or ETL. The capacity of HVACR equipment is rated by AHRI. This is especially important for split systems. An AHRI listing of the two components assures the installer and customer that the two pieces will work properly together and perform as listed by AHRI. When a unit is listed by a certifying agency, their certifying mark is applied to the unit. Equipment is often listed by more than one certifying agency (Figure 89-1).

Figure 89-1 This unit's performance has been certified by AHRI; it also meets Energy Star efficiency standards and is listed by UL.

89.5 CODE ORGANIZATIONS

The three main code-writing organizations are the National Fire Protection Association (NFPA), the International Code Council (ICC), and the International Association of Plumbing and Mechanical Officials (IAPMO). Each organization is responsible for several codes. The NFPA's focus is on fire prevention. NFPA codes are typically branded as "national" codes. For example, the NFPA writes the National Electrical Code and the National Fuel Gas Code. The ICC's focus is toward construction and development. ICC codes are branded as "international" codes. ICC codes used in HVACR include the International Building Code, the International Residential Code, the International Mechanical Code, the International Fuel Gas Code, and the International Energy conservation Code. The IAPMO focuses on plumbing and mechanical systems. Their codes are branded as "uniform" codes. Their HVACR-related codes include the Uniform Mechanical Code and the Uniform Solar Energy Code.

NFPA (National Fire Protection Association)

The mission of the international nonprofit NFPA, established in 1896, is to reduce the worldwide burden of fire and other hazards on the quality of life by providing and advocating consensus codes and standards, research, training, and education. The world's leading advocate of fire prevention and an authoritative source on public safety, NFPA develops, publishes, and disseminates more than three hundred consensus codes and standards intended to minimize the possibility and effects of fire and other risks. Two codes, the National Fuel Gas Safety Code and the National Electric Code have become mainstays in the HVACR industry. The National Electric Code is truly nationally recognized, adopted, specified, and quoted.

IAPMO (International Association of Plumbing and Mechanical Officials)

The IAPMO has been protecting the public's health and safety for more than eighty years by working in concert with government and industry to implement comprehensive plumbing and mechanical systems around the world. IAPMO publishes the Uniform Mechanical Code, which is used in many locations to govern the installation of HVACR equipment. They also produce the Uniform Solar Energy Code and the Green Plumbing and Mechanical Code Supplement.

ICC (International Code Council)

The ICC is a membership association dedicated to building safety and fire prevention. ICC develops the codes and standards used to construct residential and commercial buildings, including homes and schools. The ICC's International Codes, or I-Codes, provide minimum safeguards for people at home, at school, and in the workplace. The I-Codes are a complete set of comprehensive, coordinated building safety and fire prevention codes. Building codes benefit public safety and support the industry's need for one set of codes without regional limitations. Fifty states

and the District of Columbia have adopted the I-Codes at the state or jurisdictional level. The most commonly referenced I-Codes in the HVACR industry are the International Residential Code, the International Mechanical Code, and the International Fuel Gas Code.

89.6 MECHANICAL AND GAS CODES

For many years, the codes that specified the installation of HVACR equipment have been the Mechanical and Fuel Gas Codes. Aspects such as equipment location, duct installation, and refrigerant piping are covered in the Mechanical Codes. Gas piping, combustion air, and venting are covered in the Fuel Gas Codes. The two mechanical codes most often used are the Uniform Mechanical Code by IAPMO and the International Mechanical code by ICC. The two prevalent Fuel Gas Codes are the National Fuel Gas code by NFPA and the International Fuel Gas Code by ICC.

TECH TIP

Although there are many up-to-date codes available only those codes approved by the local or state governing agents are in effect. As a result, the most current code may not have been adopted in your area. In these cases, you must follow the earlier adopted code unless you receive a waiver from the city or state allowing you to use the more current codes. Failure to get prior approval, even for a newer code, can result in your job failing an inspection and receiving a red tag.

89.7 NATIONAL ELECTRIC CODE

Closely associated with the work of UL in terms of electrical safety is the National Electrical Code, sponsored by the National Fire Protection Association (NFPA). The original code was developed in 1897 as a united effort of various insurance, electrical, architectural, and allied interests. Although it is called the National Electrical Code, its intent is to guide local parties in the proper application and installation of electrical devices. It is the backbone of most state or local electrical codes and ordinances.

The most current code is 2011. The code specifies wiring methods and procedures necessary for the safe installation and service of electrical systems and equipment. Sections of the NEC that are particularly appropriate for air-conditioning installation are sections 310, Conductors for General Wiring; 430, Motors Motor Circuits and Controllers; and 440, Air Conditioning and Refrigeration Equipment.

89.8 INTERNATIONAL RESIDENTIAL CODE

The International Residential Building Code is written by ICC. It is a comprehensive, stand-alone residential construction code that has been adopted by many states and municipalities. It is often used instead of separate plumbing, me-

chanical, gas, and electric codes for one- and two-family dwellings. This code encompasses all aspects of residential construction, including all aspects of HVACR mechanical systems.

89.9 MAJOR PHASES OF INSTALLATION

Installations can be broken down into phases, based on the required skills and the work performed. The major phases of installations are as follows:

- Equipment placement
- Ductwork installation
- Piping installation (refrigerant, water, and gas)
- Electrical connection
- Evacuation and charging
- Start and check

In larger companies, these phases are often performed by separate crews. The equipment placement and duct installation is typically done by the same crew. The erection of piping is sometimes performed by installers who specialize in piping. Electrical connections are frequently done by crews who primarily handle electrical wiring and installation. Frequently the wires are pulled in place by the equipment installers, but the connections are made by the wiring and controls crew. Evacuation, charging, and start-up are usually performed by crews who specialize in refrigeration.

Any number of these phases can be performed by the same technicians in some companies. In smaller companies, a single installation crew is responsible for all phases of installation.

89.10 EQUIPMENT PLACEMENT

Despite what may seem to be a great many possibilities for positioning major components during installations, three factors must be considered in the placement of equipment if satisfactory installation and proper operation are to be ensured:

- Ample space must be provided for air movement around air-cooled condensing equipment to and from the condenser.
- All major components must be installed so that they may be serviced readily. When an assembly is not easily accessible for service, the cost of service becomes excessive.
- Vibration isolation must always be considered, not only in regard to the equipment itself but also in relation to the interconnecting piping and sheet metal ductwork. All manufacturers supply recommendations of the space required; these recommendations should be followed.

Figure 89-2 shows a properly placed air-cooled condensing unit. Sufficient room has been left for the passage of incoming air around and over the unit.

An example of a common error in positioning major system components is shown in Figure 89-3. A shell-and-tube

Figure 89-2 Air-cooled condensing units must be placed so that their airflow is not restricted.

Figure 89-3 Service accessibility is important in positioning major system components.

water-cooled condenser has been placed in such a position that the entire condensing unit must be moved to replace a single condenser tube. Be sure to allow room for replacement of items such as compressors, fan motors, fans, and filters. High service costs are often attributable to the poor placement of system components.

Noise is also an important factor in the placement of air-cooled condensing equipment. The discharge air transmits noise generated within the unit. It is poor practice to "aim" the condenser discharge air in a direction where noise may be disturbing, such as a neighboring window.

Vibrations set up by rotating assemblies such as compressors, fans, and fan motors can break refrigerant

Figure 89-4 Internal isolation springs inside hermetic compressor.

lines, cause structural building damage, and create noise. Vibration isolation is required on all refrigeration and air-conditioning equipment where noise or vibration may be disturbing. Almost all manufacturers use some form of vibration isolation in the production of their equipment. The compressor is the chief source of system vibration. Hermetic reciprocating compressors are usually mounted on springs inside the compressor shell (Figure 89-4). Most compressors are also externally mounted on some form of vibration-dampening material, such as the rubber bushings shown in Figure 89-5.

Figure 89-5 Hermetic compressor mount on rubber isolation bushings.

TECH TIP

Some metropolitan areas have maximum-noise-level ordinances affecting HVACR equipment. These ordinances may affect the equipment selected and equipment placement to keep the sound level within the ordinance guidelines. Check with your local building office regarding noise level ordinances.

When air-conditioning units with compressors are suspended from the roof or in the upper stories of a multistory building, vibration isolators may be used (Figure 89-6). These spring suspensions isolate unit vibration from the surface from which the unit is suspended.

Isolation pads designed specifically for vibration dampening (Figure 89-7) are placed under the equipment to reduce the transmission of vibrations to the surface on which the unit is resting. This type of material is designed to dampen the vibration from a given amount of weight per square inch of area. Consult the manufacturer's installation recommendations when selecting vibration isolation materials.

Vibration eliminators are installed in the discharge and suction lines of the compressor to isolate compressor movement and vibration from the refrigerant lines (Figure 89-8). The eliminator consists of a flexible corrugated metal hose core with an overall metal braid. The braid will allow some sideways movement of the flexible material, but no expansion or contraction. This type of eliminator is normally installed in the compressor refrigerant lines as close to the compressor as practical. It is particularly effective on installations where the compressor and condenser are

Figure 89-6 Hanging spring suspension mounts.

Figure 89-7 Isolation pads in various sizes.

on different bases yet quite close together. The vibration isolator should be placed in the line so that the movement it absorbs is in a plane at right angles to the device. Do not place this unit in a position that will put tension on it, as its useful life will be shortened.

Figure 89-8 (a) Vibration eliminator; (b) internal ribs that allow a vibration damper to flex; (c) typical installation of a vibration damper as it is installed on a refrigeration system.

SERVICE TIP

When hanging an air handler from the attic rafters, it can be set on wooden blocks first so it can be leveled before attaching the hanging straps. This will make leveling the unit much easier. In addition to the common sheet metal straps, there are other hanging systems, including cable and threaded rods, which make hanging and leveling much easier and faster.

Figure 89-9 Blower motors are mounted to the blower housing using rubber bushings.

The blower assembly in furnaces and air handlers is a possible source of vibration. Most manufacturers isolate the fan and fan motor inside the unit with rubber mounts (Figure 89-9). When furnaces or air handlers are installed in

the attic, suspending them (Figure 89-10) will isolate them from the ceiling and reduce sound transmission. The unit may also rest directly on the ceiling joists if vibration isolation pads are used (see Figure 89-7).

SERVICE TIP

Never rest a unit directly on the ceiling joists or a platform fastened to the ceiling joists without using vibration-isolation pads. Placing the unit directly on the ceiling joists turns the entire ceiling into a sounding board that amplifies the unit noise.

89.11 BASEMENT AND CLOSET INSTALLATION CHECKLIST

The following checklist highlights important considerations when installing equipment in basements, closets and alcoves. Figure 89-11 illustrates the listed specifications. Code numbers follow each item in parentheses.

- Appliances shall not be installed in storage closets. (IRC G2406.2)
- There must be a minimum of 3 in clearance along the sides, back, and top of equipment. (IRC M1305.1.1)
- The space must be at least 12 in wider than the equipment. (IRC M1305.1.1)
- Furnaces must have a minimum 6-in clearance in front of the firebox. (IRC M1305.1.1)

Figure 89-10 Suspended air-handling unit.

Figure 89-11 Specifications for equipment installed in a closet.

- The door to a closet must be at least 24 in wide. (IRC M1305.1.2)
- Equipment must fit through the door. (IRC M1305.1.2)
- A minimum service space is required. It should be located by the service access panel, 30 in deep and the height of the appliance, but not less than 30 in high. (IRC M1305.1.2)

- Where damage to building components will occur from water overflow, an auxiliary drain pan is required for condensing equipment, including air conditioners, heat pumps, and 90 percent furnaces. This provision is normally applied to attic installations but can also be applied to any installation where water can damage the floor or walls. (IRC M1411.3.1)
- Electrical disconnect must be within sight of the unit. (IRC Table E4101.5)
- For combustion appliances, ensure that adequate combustion air is provided. (IRC G2407) (For more details, see Unit 51, Gas Furnace Installation.)

89.12 ATTIC INSTALLATION CHECKLIST

The following checklist highlights important considerations when installing equipment in attic spaces. Figure 89-12 illustrates the listed specifications. Code numbers follow each item in parentheses.

- The minimum clear opening is 20 in x 30 in. (IRC M1305.1.3)
- The equipment must fit through the opening. (IRC M1305.1.3)
- There must be a solid floor at least 24 in wide from the entrance to the unit. (IRC M1305.1.3)
- There must be a light switch at the entryway. (IRC M1305.1.4.3)
- There must be a light and receptacle near the unit. (IRC M1305.1.4.3)
- There must be an electrical disconnect within sight of the unit. (IRC E4101.5)
- Maximum distance must be 20 ft from the entry to the unit. However, if the passageway is at least 6 ft high

Figure 89-12 Specifications for equipment installed in an attic.

and 22 in wide, the distance may be up to 50 ft. (IRC M1305.1.3)

- A minimum 30 in x 30 in level service platform is required by the service panel of the equipment. (IRC M1305.1.3)
- An auxiliary drain pan is required for condensing equipment, including air conditioners, heat pumps, and 90 percent furnaces. Although there are several approved methods for protection, the most common is to use a pan with a separate drain installed underneath the equipment. The pan must be at least 1.5 in deep and 3 in larger in all dimensions than the equipment. (IRC M1411.3.1)
- The appliance should be supported above the flood rim of the auxiliary drain pan. (IRC M1411.3.3)
- For combustion appliances, ensure that adequate combustion air is provided. (IRC G2407) (For more details, see Unit 51, Gas Furnace Installation.)

89.13 CRAWLSPACE INSTALLATION CHECKLIST

The following checklist highlights important considerations when installing equipment in crawlspaces. Figure 89-13 illustrates the listed specifications. Code numbers follow each item in parentheses.

- The minimum rough framed opening for the access door is 22 in x 30 in. (IRC M1305.1.4)
- The equipment must fit through the opening. (IRC M1305.1.4)

Figure 89-13 Specifications for equipment installed in a crawlspace.

- The passageway to the equipment must be at least 22 in wide and 30 in high. (IRC M1305.1.4)
- If the passageway is 12 in or more below grade, the walls must be lined with masonry or concrete extending 4 in above grade. (IRC M1305.1.4)
- Maximum distance must be 20 ft from the entry to the unit. However, if the passageway is at least 6 ft high and 22 in wide, the distance may be unlimited. (IRC M1305.1.4)
- If excavation is required, there should be a 6 in clearance under the unit, 12 in clearance on all sides, and a 30 in service clearance at the appliance. (IRC M1305.1.4.2)
- A minimum 30 in x 30 in level service space is required by the service panel of the equipment. (IRC M1305.1.4)
- Equipment supported from the ground must be on a concrete slab at least 3 in above the adjoining ground. (IRC M1305.1.4)
- Equipment suspended from the floor shall have a ground clearance of at least 6 in. (IRC M1305.1.4)
- A light switch must be located at the entryway. (IRC M1305.1.3)
- A light and receptacle must be located near the unit. (IRC M1305.1.4.3)
- The electrical disconnect must be located within sight of the unit. (IRC E4101.5)
- For combustion appliances, ensure that adequate combustion air is provided. (IRC G2407) (For more details, see Unit 51, Gas Furnace Installation.)

89.14 GARAGE INSTALLATION CHECKLIST

SAFETY TIP

Although code does allow installation of HVACR equipment in a garage under certain conditions, there are safety considerations that are best addressed by not locating HVACR equipment in a garage. The first is the possibility of igniting gasoline vapors. The second is the possibility of circulating carbon monoxide produced by vehicles through the system duct work. Simply not locating the equipment in the garage is the best safeguard to both of these potentially fatal safety concerns.

Figure 89-14 Specifications for a unit installed in a garage.

Garage installation of HVACR equipment is not recommended. If it cannot be avoided, the following checklist will reduce the associated hazards. Figure 89-14 illustrates the listed specifications. Code numbers follow each item in parentheses.

- Equipment should be located at least 18 in above the garage floor. (IRC M1307.3)
- Equipment shall be protected from impact. (IRC M1307.3.1)
- Systems supplying the living spaces shall not draw air from or supply air to the garage. (IRC M1601.6)
- Ductwork should be constructed of 26-gauge sheet metal. (IRC R302.5.2)
- Ductwork shall have no opening to the garage. (IRC R302.5.2)

89.15 OUTDOOR UNIT INSTALLATION CHECKLIST

The following checklist highlights important considerations when installing a condensing unit outside. Figure 89-15 illustrates the listed specifications. Code numbers follow each item in parentheses.

- Outdoor unit shall be raised at least 3 in above the ground. (IRC M1403.2)
- Refrigerant vapor lines shall be insulated with R-4 insulation. (IRC M1411.5)
- Outdoor refrigerant access ports shall have locking caps. (IRC M1411.6)
- Electrical disconnect must be located within sight of the unit. (IRC E4101.5)
- Refrigerant lines running inside the wall should be protected by steel shield plates. (IRC M1308.2)

Figure 89-15 Specifications for an outdoor unit.

89.16 ACCA QUALITY INSTALLATION STANDARD

The ACCA Quality Installation Standard outlines the procedures to follow to achieve the system performance and efficiency the equipment was designed to provide. The standard breaks the process down into four general aspects of system installation: design, equipment installation, distribution, and documentation. The Quality Installation Specification lists acceptable methods of achieving the desired results and the type of documentation the contractor should provide to comply with it. The specific areas addressed by the standard and the units in this text that cover those areas are listed in Table 89-1.

89.17 DUCTWORK

Ductwork is an often overlooked part of a system installation. Customers often focus on the equipment ratings and don't pay enough attention to the workmanship of the installation. The equipment cannot deliver its rated capacity and efficiency if it is connected to a bad duct system. Since the ducts distribute the conditioned air to the house, if they are improperly sized, leaky, or poorly insulated, the house will not be properly conditioned. Further, the energy cost of poorly designed, leaky, and poorly insulated ducts is usually much higher than the difference between the operating cost of an entry-level unit and a high-efficiency unit. A good duct system must be properly designed, installed, sealed, insulated, tested for leaks, and balanced. Duct systems should be sized based on the heat load of the house. Ducts should be sealed with products made expressly for that purpose. They should be UL 181 rated for the specific type of duct material being used. All ductwork should be insulated and have a vapor barrier to prevent condensation. Duct insulation should have a minimum R value of 6. Ducts located in attics should be insulated with a minimum R value of 8. After installation, ducts should be pressurized and leak tested. Finally, the airflow delivery to the different rooms of the house should be checked and the system balanced to deliver the correct airflow.

The details of each of these steps are covered in the text. Unit 70, Residential Load Calculations, covers heat load calculations and equipment sizing. Unit 71, Duct System Design, covers duct design. Unit 46, Duct Installation, covers duct installation, insulation, and leak testing. Unit 73,

Testing and Balancing Air Systems, covers the procedures for balancing the airflow through the duct system.

89.18 PIPING

The art of making flared, soldered, and brazed connections in copper tubing has been discussed in Unit 24, Piping and Tubing, and Unit 25, Soldering and Brazing. The procedures for sizing refrigerant lines were discussed in Unit 26, Refrigerant System Piping. Several important points should be remembered while actually erecting the system piping.

When hard copper tubing is selected for refrigerant piping, it is recommended that silver alloy brazing materials be used. These alloys have flow points in the range of 1,100°F–1,400°F. To attain these temperatures, oxyacetylene equipment is required (Figure 89-16).

The use of nitrogen is recommended to keep the interior of the pipe clean during the brazing process. Nitrogen brazing requires a nitrogen regulator and pressure-relief valve (Figure 89-17). During brazing, the surface of the copper will reach a temperature at which the metal will react with oxygen in the air to form a copper oxide scale. If this scale forms

Figure 89-16 Oxyacetylene torch used for brazing.

Figure 89-17 Nitrogen regulator with pressure-relief valve.

on the interior surface of the pipe, it might be washed off by the refrigerant and oil circulating in the system. The scale can clog strainers or capillary tubes and will plug orifices.

This scaling can be prevented by replacing the air in the pipe with nitrogen or carbon dioxide. Flowing nitrogen or carbon dioxide through the pipe prevents scaling because the nitrogen and carbon dioxide are inert gases and will not combine with copper, even under high-temperature conditions. The pipe interior will remain clean during brazing and no scale is formed, though discoloration may occur with overheating.

TECH TIP

When using an inert gas as a purge to prevent oxide formation, only a very slight flow of gas is required. Excessively high flow rates may create enough internal pressure to cause pinholes during the brazing process as the gas is forced out through the joint.

Figure 89-18 shows the connections for introducing nitrogen into the system during the brazing operation. Connect the nitrogen bottle to the liquid-line service Schrader valve with a refrigeration hose. A slight pressure is

Figure 89-18 System connections for nitrogen brazing.

admitted into the tubing using the pressure-regulating valve on the nitrogen bottle. This is just enough pressure to ensure that air will be forced from the pipe. If the nitrogen flow can be felt on the palm of the hand, the flow is sufficient. This nitrogen pressure is kept in the tubing throughout the entire brazing operation.

CAUTION

Never use oxygen or acetylene to develop pressure when checking for leaks. Oxygen will cause an explosion in the presence of oil. Acetylene will decompose and explode if the regulator pressure is over 15–30 psig (30–45 psia or 210–310 kPa).

Clean pipe is essential in refrigeration installation. The use of nitrogen or carbon dioxide is extremely important in the brazing operation to ensure scale-free interior pipe walls.

The temperatures during brazing operations can warp metals and burn or distort internal elastomeric or plastic components. Many valves have rubber O-ring seals that can be damaged by excess heat. After they are melted, often the only fix is to replace the valve. The valves can be protected with a wet rag wrapped around the body (Figure 89-19). The water absorbs the heat that flows to the valve body during the brazing operation. By keeping the rag wet, the valve and its component parts are protected from heat damage. Heat-absorbing pastes and sprays are available to control heat and protect components (Figure 89-20). Using a heat-absorbing paste or spray is often necessary in places where wet rags will not go.

After all interconnecting tubing has been assembled, nitrogen is introduced into the system for leak testing. By using nitrogen, the pressure in the system may be built up to approximately 100 psig for leak testing.

CAUTION

Never pressurize the system above the low-side system test pressure (Figure 89-21) or above 150 psig for systems with hermetic compressors! Overpressurizing a compressor shell can cause catastrophic shell failure, turning the compressor shell into a bomb!

When using nitrogen to pressurize the system, leaks may be detected with soap bubbles and ultrasonic leak detectors. Halide torches and electronic leak detectors will not work with nitrogen. A small amount of R-22 or a non-ozone-depleting refrigerant may be used with the nitrogen as a trace gas if you wish to use an electronic leak detector. Since nitrogen is an inert gas, the nitrogen must be vented and the system evacuated after it has been determined to be leak free.

Figure 89-19 Valves can be protected from damage during brazing with a wet rag.

Figure 89-20 Heat-absorbing paste or spray gel is easier to use in many situations than a wet rag.

Figure 89-22 Suction lines should be insulated to avoid condensation and loss of system efficiency.

TECH TIP

Venting mixtures of R-22 and nitrogen used as a holding charge or a leak test gas does not violate the prohibition on venting ozone-depleting substances. However, other ozone-depleting refrigerants may not be used as trace gases.

Figure 89-21 This system should not be pressurized past 144 psig when leak testing.

TECH TIP

Moisture has been associated with the formation of mold and mildew in buildings. Condensate can be a significant source of moisture. It is very important that tubing insulation on refrigerant lines be sealed at the joints so that condensate cannot form.

Figure 89-23 Pipe hangers used to support insulated pipes.

The insulation must be of good quality so that the temperature of its exterior surface will never drop below the dew point of the surrounding area. If the system is a heat pump, make sure the insulation is approved for use with heat pumps. It must also be well sealed, so that air and the moisture it contains cannot reach the pipe, thus causing condensation underneath the insulation.

An example of a typical pipe hanger that might be used on a small commercial refrigeration installation is shown on the right in Figure 89-23. This hanger serves as a vibration isolator as well as a pipe supporter. A short length of light-gauge rustproof metal is used to form a cradle to support the insulated pipe. A metal strap has been attached to this length of metal. In some cases it is merely wrapped around the length of sheet metal. The free end of the strap is then fastened to the joist or ceiling. The insulation in such a hanger will act as the vibration isolator. The purpose of the short length of metal is to prevent the thin strap from cutting the insulation.

The hanger shown on the left in Figure 89-23 has a height-adjustment feature for leveling or pitching the pipe if required for oil return. This type of hanger can be used with or without insulation.

89.19 ELECTRICAL CONNECTIONS

The service technician who installs the refrigeration equipment is sometimes responsible for the final wiring connections between the installed unit and the fused disconnect switch. All electrical power to the refrigeration unit must pass through this switch. When this switch is pulled, or opened, all electrical power to the unit must be disconnected. This same disconnect switch also contains fuses, which will interrupt the flow of current whenever a severe electrical overload occurs. This mechanism is a protection against fires and explosions and also against electrical shocks to people.

Three components of the power wiring to the unit that must be properly sized are the conductor, the disconnect, and overload protection devices.

Conductors are sized by current carrying capacity and voltage drop. Voltage-drop calculations are normally not necessary for runs under 100 ft if the minimum wire sizing charts in Section 310 of the NEC are followed. A conductor should be selected from the wire sizing charts whose current rating is equal to or greater than the minimum circuit ampacity listed on the unit data plate (Figure 89-24).

Air-conditioning units must have a readily accessible disconnect within sight of the unit (Figure 89-25). The disconnect

Figure 89-24 The minimum circuit ampacity is in yellow; the maximum fuse size is in green. The wire should be sized for no less than 31.5 amps; the fuse should be no larger than 50 amps.

Figure 89-25 All equipment should have a disconnect switch within sight of the unit and readily accessible.

current rating should be 115 percent of the minimum circuit ampacity. The overload protection should be no larger than the maximum fuse size shown on the data plate (see Figure 89-24). Standard fuses and circuit breakers are subject to nuisance trips from the momentary high inrush current when compressors start. The overcurrent protection for systems with compressors should be either time-delay fuses or an HVACR-rated circuit breaker because they allow the compressor to start without tripping.

CAUTION

Although codes require that all electricity to equipment be able to be disconnected at a single disconnect point, this is not always the case. Occasionally, host installation wiring may bring voltage into equipment that does not go through the disconnect. Before you begin working inside electrical panels on equipment, make certain that there is no voltage. Use your voltmeter to test all connections between each power connection and each power connection and a known ground.

89.20 SYSTEM EVACUATION

The refrigerant system needs to be leak tested and evacuated before it is charged. Nitrogen is commonly used as a leak test gas after making all the refrigerant piping connections. Any nitrogen left in the system from leak testing should be released before proceeding to evacuate the system. Connecting a vacuum pump to a system with a nitrogen charge will blow the oil out of the vacuum pump, making a mess and possibly damaging the vacuum pump.

TECH TIP

Since the air is 78 percent nitrogen, it is perfectly legal to vent the nitrogen holding charge. Venting de minimus mixtures of R-22 and nitrogen used for leak testing is also permitted by the EPA. However, nitrogen mixed with other ozone-depleting refrigerants may NOT be vented.

Be careful to release only nitrogen charges. Some systems, such as commercial refrigeration systems, come with only a nitrogen holding charge, which must be released before charging (Figure 89-26). The service valves on these units must be cracked to release the nitrogen. On the other

Figure 89-26 This equipment has a nitrogen holding charge.

CONTAINS HCFC – 22			DESIGN PRESSURE	
FACTORY CHARGE			278	HI PSIG

1 PH	60 HZ		MIN 197	MAX 253

Figure 89-27 This unit holds 12 lb, 8 oz of HCFC 22 refrigerant.

hand, air-conditioning systems usually have a factory refrigerant charge that should not be released (Figure 89-27). These valves are typically shipped front-seated. They should not be turned until after the lines and coil have been evacuated. Read the installation instructions carefully to determine which type of system you are installing.

The system should be evacuated from both the high and low sides of the system to the vacuum level specified by the manufacturer, typically 500 microns or lower. The only way to ensure the proper level of evacuation is to use a vacuum gauge to verify the results. The amount of time required varies depending upon the size of the system and the length of refrigerant piping. However, clean systems rarely require longer than an hour unless they are very large.

SERVICE TIP

Many technicians save time by leak testing and evacuating the system before making the electrical connections. The system will typically be fully evacuated by the time they finish making all the electrical connections, so no additional installation time is required to properly evacuate the system.

89.21 CHARGING THE SYSTEM WITH REFRIGERANT

Charging the system with refrigerant is one of the most commonly performed tasks in the field. Unfortunately, it is often done incorrectly. Improper charging is most often due to the technician's failure to read and follow the manufacturer's instructions.

Packaged Units

Packaged units normally do not require charging for new installations because they are charged at the factory. In the event a packaged unit does require charging, you should first determine if the unit was shipped without a charge or if the charge leaked out. If the charge leaked out then the first step is to locate and repair all leaks. After the system is leak-tight, it should be evacuated and charged. The amount and type of refrigerant will be on the data plate (see Figure 89-27). The unit should not be operating while the refrigerant is weighed in. For units that hold more than 1 lb of refrigerant, the charge should be weighed in as a liquid into the king valve or liquid-line service valve. For units that hold

Figure 89-28 The unit arrives with the valves front-seated, as shown on the left; turning the valves counterclockwise opens them and releases the refrigerant.

less than 1 lb, the refrigerant should be weighed in as a gas into both sides of the system at once.

Split Systems

Split systems usually do require some adjustment to the refrigerant charge to account for their refrigerant lines. Most manufacturers ship their condensing units with enough charge for the outdoor unit, the indoor coil, and a set length of refrigerant line. This charge is held in the condensing unit with split-system shutoff valves (Figure 89-28). These valves are front-seated when the unit is shipped. The Schrader access fittings on these valves are always open to the refrigerant line regardless of the valve's position. The shutoff valves are opened only after installing, leak testing, and evacuating the refrigerant lines and indoor coil.

CAUTION

Do not overtighten the installation valves when opening them. Stop turning the valve as soon as you feel increased resistance or see the top of the plug. A lock ring is all that keeps the valve plug in. Overtightening it in the counterclockwise direction will result in the valve plug shooting out at a pressure exceeding 100 psig, and all the refrigerant will come with it!

Opening the valves allows the refrigerant that is trapped in the condenser to travel throughout the system. If the actual line length is exactly the same as the manufacturer's assumed line length, you are done. If the lines are longer than the assumed length, you will need to add refrigerant. If the lines are shorter, you will need to remove refrigerant. The amount of assumed line length varies from 15 ft to 30 ft, depending upon the manufacturer. Many systems now include information on the unit that lists the assumed line length and gives the required per foot charge adjustment (Figure 89-29).

Figure 89-29 The assumed line length of 25 ft is included in the charging instruction that are included on this unit's service panel.

Table 89-2 Liquid Line Charge Allowance

Liquid Line Diameter (in)	Ounces per Foot of Liquid Line
1/4	0.3
5/16	0.4
3/8	0.6
1/2	1.2
5/8	1.9

To calculate the amount of refrigerant needed:

1. Find the extra line length by subtracting the assumed length from the actual length.
2. Look up the per-foot charge for the size liquid line used.
3. Multiply the extra line length by the charge per foot to find the amount of additional charge required.

Table 89-2 shows the per foot charge required for liquid lines of various sizes. Note that an allowance is made only for the liquid line. There is not enough refrigerant in the suction line to calculate.

Under normal charging conditions, the refrigerant cylinder will be at ambient temperature and corresponding pressure. When the unit is operating, the refrigerant cylinder pressure will usually be below the head pressure of the condenser and above the back pressure of the evaporator. The easiest way to add the small amount of refrigerant needed for the line allowance is to add vapor to the suction side with the unit operating. For all refrigerants besides zeotropes, the refrigerant should be leaving the cylinder as a vapor with the cylinder in the upright position (Figure 89-30).

For zeotropes, the refrigerant must leave the cylinder as a liquid (Figure 89-31). This poses a problem because liquid should not be charged into the suction side of a system. The liquid refrigerant must be restricted between the cylinder and the system to safely add a zeotropic refrigerant with the unit operating. This can be accomplished with a charging device that is put in line with the cylinder (Figure 89-32) or by throttling the refrigerant using the hand valve on your gauges. Caution must be taken when charging a system with liquid refrigerant so that the compressor is not overloaded or slugged with liquid. Allowing too much liquid to enter the suction line is a fast way to kill a compressor.

Figure 89-30 The refrigerant leaving this cylinder will be a gas when the cylinder is upright.

Figure 89-31 The cylinder on the left must be inverted to deliver liquid; the cylinder on the right delivers liquid while in the upright position.

Figure 89-32 This device flashes off liquid to gas, allowing the refrigerant to leave the cylinder as a liquid even when charging into the suction line. (Courtesy of HVAC Department, Terra Community College, Fremont, Ohio)

TECH TIP

Many of the systems that are in service today are overcharged. There is a feeling among some technicians that a little extra refrigerant should be added to the system just in case there is a leak. If you suspect a leak, fix the leak; do not overcharge the system. Excessive refrigerant charges can be as detrimental to the equipment and to the equipment performance as undercharged equipment.

89.22 PRESTART CHECKS

The initial start-up is a critical time in a unit's life. Making certain that the installation meets all the manufacturer's specifications is a good way to prolong the life of the equipment. Installations that are not up to spec often lead to premature equipment failures that could have been avoided by taking a little extra time before starting the unit for the first time.

It is a good idea to have a routine to follow for initial start-up. Using a routine saves time and ensures that all necessary items are covered. Figure 89-33 is a general-purpose initial pre-start checklist. If the manufacturer has supplied a suggested start-up procedure, follow it! The installation and start-up directions are normally inside the unit or shipping carton.

Clearances

Check to see that an adequate amount of space has been left on all sides of the unit. The specific distances for a particular unit can be found in the installation instructions. Clearances on air-conditioning condensing units are required for proper airflow and adequate service access. Heat pump condensing units also require clearance from the ground in certain locations to elevate them above ice and snow. Also, all outdoor units should be protected from roof water runoff. This can be accomplished by locating the unit outside of the roof overhang, by using gutters to divert the water flow, or by using a strip of angled flashing installed on the edge of the roof above the unit. Furnaces require clearances from combustible materials. Tables 89-3 and 89-4 list typical clearances for air-cooled condensers.

Table 89-3 Vertical Discharge Air-Cooled Condensing Units

Type of Clearance	Distance (in)

Figure 89-33 General-purpose initial pre-start checklist.

Table 89-4 Horizontal Discharge Air-Cooled Condensing Units

Type of Clearance	Distance (in)
Clearance from all sides where air is discharged	48
Clearance from any side of the unit where air is drawn in	18
Clearance from any service access panel	30

Mechanical Precheck

Prestart mechanical checks should include the following:

- Visually look for and remove all packing and shipping supports and bolts.
- Make sure that a clean air filter is in place inside.
- Pour water in the evaporator drain pan to confirm that it drains correctly.
- Pour water in the secondary drain pan to confirm that it drains correctly.
- Check the thermostat with a small level.

- Use a level to check the level of the unit.
- Spin the condenser fan by hand to make sure it rotates freely.
- Check to see that the charging valves on the condensing unit are back-seated.
- If they are not, then you will need to evacuate the lines and evaporator coil *before* opening them.
- Connect refrigerant gauges to ensure that the unit has a charge. If there is no charge, you will need to determine why before proceeding.
- Check all line connections for leaks.

Electrical Precheck

Electrical checks to be completed before starting the unit should include the following:

- The power wire should be *copper* (not aluminum).
- The power wire connections should be tight.
- Make certain that the unit is grounded.
- There should be a disconnect switch for each piece of equipment *in sight* of the equipment.
- Check that the overcurrent protection is not more than the maximum size stated on the unit's nameplate.
- Use the wiring diagram to check the low-voltage connections. With the thermostat and disconnect switch turned off, check the voltage going into the disconnect switch. It should be within ± 10 percent of the nominal voltage rating on the nameplate. If it is not, do not turn the disconnect switch on.
- Turn the disconnect switch on and check the voltage available to the unit. It should be within the minimum and maximum voltages stated on the unit data plate.

Gas Precheck for Combustion Appliances

- Check that gas line has a shutoff valve, drip tee, and union.
- Check to see that all gas piping is properly supported.
- Check for combustion air provisions.
- Check to see proper vent materials and connections.

89.23 INITIAL START-UP

A quick check of unit operation should be done immediately after start-up to verify that it is operating safely. For all types of systems, check the operating voltage and compare it to the system data plate. If the voltage was correct before start-up but drops below the unit's minimum voltage rating after starting, either the wire is too small or there is a bad connection. In either case, the unit must be shut off and the problem must be corrected. If the voltage is within the manufacturer's specifications, check the operating current against the data plate and make sure that it is not too high.

Do a quick check of the refrigerant pressures. At this point, you just need to verify that they are within safe op-

erating limits. If the suction pressure starts to pull down to 0 psig, there is a refrigerant restriction that must be corrected. Shut down the unit and look for possible restrictions. Start by double-checking the position of the line installation valves. Check to see that the high-side pressure is not too high. As a general rule, R-22 pressures over 300 psig or R-410A pressures over 450 psig indicate a problem. Do not let a unit operate for an extended period of time above these pressures. Excessive head pressures could be the result of poor airflow over the condenser or an overcharge. On a new unit, poor airflow would most likely be caused by incorrect condenser fan rotation, the condenser fan not operating, or coils blocked by shipping plastic or cardboard. In any event, the high side must be brought down to a safe level. On a three-phase unit with a scroll compressor, if the compressor starts but the high-side and low-side pressures remain the same, the compressor is most likely turning backwards. Shut off the power and reverse two of the power legs at the compressor contactor.

Once the unit has started and you have verified that it is operating safely, you can measure the system operational data and check it against the manufacturer's specifications. Before checking the system operating pressures and temperatures, the unit should operate long enough to bring the house close to normal AHRI inside design conditions: 80° dry bulb, 67° wet bulb. While the unit is operating, check the total system airflow by checking the static pressure across the blower and comparing it to the manufacturer's specifications. Next, check the airflow at the registers and compare it to the design airflow. Now check the system operational data, including high- and low-side pressures, superheat, subcooling, temperature drop across the evaporator, and temperature rise across the condenser. Compare these data to the manufacturer's specifications. These data are usually found in the installation instructions and on the equipment service panels. Units with expansion valves often have a subcooling specified right on the condenser nameplate (Figure 89-34). Figure 89-35 is a general-purpose initial prestart and start-up checklist.

Figure 89-35 General-purpose initial start-up checklist.

UNIT 89—SUMMARY

A successful installation begins with reading the instructions and applicable codes. National organizations that set installation standards include AHRI, ASHRAE, ASME, UL, and NFPA. Phases of installation include the following:

- Equipment placement
- Ductwork installation
- Piping installation (both refrigerant and water)
- Electrical connection
- Evacuation and charging
- Start and check

Equipment should be located where it can be serviced. Air-cooled condensers should be placed so that

the airflow to them is not obstructed. All piping should be supported. Refrigerant lines should be purged with nitrogen during brazing to prevent oxidation. All equipment should have an electrical disconnect within sight of the equipment. Power wiring should be sized to carry the minimum circuit ampacity marked on the unit data plate. The circuit overcurrent protection should not exceed the maximum fuse size listed on the unit data plate. Refrigeration systems should be evacuated to 500 microns before charging. A careful prestart-up inspection and initial system performance check can help avoid future problems. Using a checklist to document the steps taken during the prestart inspection and initial start-up can ensure that all steps have been taken. Regardless of equipment type, a good installation is the best way to ensure long equipment life, reliable operation, and energy efficiency.

WORK ORDERS

Service Ticket 8901

Initial System Start-up

Equipment: Small Split-System Air-Conditioning Unit in Commercial Setting

A technician is performing a prestart-up inspection and notices that the system's minimum circuit ampacity is listed as 15 A and the unit is wired with 14-gauge wire. The NEC wire sizing chart shows that 15 A is the most that wire will carry. The technician also notes that the power wire has been run a long way because the unit is over 200 ft from the power panel. The system nominal voltage rating is 208–230 V with a minimum of 190 V and a maximum of 250 V. The voltage check with the unit off shows 208 V available. The technician is wary because the voltage is in the lower end of the acceptable range. When the unit is started, the line voltage drops to 188 V and the technician shuts the system off. The technician recommends that the power wire be replaced with a larger gauge wire to reduce the voltage drop and keep the unit operating consistently above the minimum voltage rating.

Service Ticket 8902

Initial System Start-up

Equipment: Split-System Residential Air-Conditioning Unit

A technician is sent to perform an initial system start-up. During the prestart check the technician notices that the refrigerant line installation valves are still front-seated. The technician decides to evacuate the lines and coil before opening the valves in case they were not evacuated properly. The lines and coil are blanked off after they are evacuated to 500 microns. The vacuum holds, so the technician opens the refrigeration line installation valves.

Service Ticket 8903

Customer Request: Packaged Unit Replacement

Equipment Type: Residential Packaged Air Conditioner with Vertical Condenser Air Discharge

An estimator is sent to collect information to bid a job replacing a packaged air-conditioning unit. Upon arrival, the estimator notices that the old system is located under a porch, has an over-under duct configuration, and has a horizontal discharge condenser. The systems their company normally sells have side-by-side duct connections and a vertical discharge condenser. The estimator returns and explains that either a different system must be used or the system must be relocated to allow for proper condenser airflow and major duct modifications.

Service Ticket 8904

Customer Request: Heat Pump Installation

Equipment Type: Residential Split-System Heat Pump in Northern Climate

A technician is sent to install a split-system heat pump and notices that no provision has been made to keep the outdoor unit above the snow level in the winter. The company has never installed a heat pump before and was planning on setting the outdoor unit on the concrete pad like an air-conditioning condensing unit. The technician shows the foreman the installation instructions that show a metal frame elevating the unit above the top of the snow. The technician fabricates a galvanized metal frame that holds the outdoor unit 3 ft off the ground.

Service Ticket 8905

Customer Request: Gas Furnace Replacement

Equipment Type: 80 Percent Induced-Draft Furnace Replacing Existing Natural-Draft Furnace

A technician is sent to replace an existing natural-draft furnace with a new 80 percent induced-draft furnace. The technician notices that the existing furnace uses a 7-in single-wall metal vent connector leading to a masonry chimney. The new furnace has a vent collar of 5 in. The new furnace installation instructions clearly say that single-wall pipe should not be used and that masonry chimneys should not be used unless a metal liner is used. The installer recommends lining the masonry chimney with a metal liner and replacing the old 7-in single-wall vent connector with 5-in double-wall pipe.

UNIT 89—REVIEW QUESTIONS

1. List the associations that establish national standards for the HVACR industry.
2. What is the function of AHRI?
3. What does the UL specialize in?
4. List all major phases of system installation.
5. What factors must be considered in equipment placement?
6. Outline the correct brazing procedure for hard copper refrigeration piping.
7. What electrical rating on a unit data plate is useful for sizing the power wire for the unit?
8. What electrical rating on the unit data plate is useful for sizing the circuit breaker for the unit?
9. Use the information on the data plate in Figure 89-24 to determine the minimum current rating for sizing the power wire to the unit.
10. Use the information on the data plate in Figure 89-24 to determine the minimum current rating for the unit disconnect.
11. Use the information on the data plate in Figure 89-24 to determine the maximum circuit breaker size for the unit.

12. What type of overcurrent protection is used with air-conditioning equipment?
13. How should ductwork be sealed against air leaks?
14. How can vibrations and sound transmission in HVACR equipment be minimized?
15. Use Figures 89-27 and Table 89-2 to determine the correct amount of additional charge for a new split system with a 40-ft line set and a $\frac{3}{8}$ -in liquid line. The factory charge includes enough refrigerant for 15 ft of line.
16. What position are the unit installation valves in when the unit is shipped?
17. When installing a split system, what should be done prior to opening the installation valves?

UNIT 90

Planned Maintenance

OBJECTIVES

After completing this unit, you will be able to:

1. describe the four phases of a planned maintenance service call.
2. discuss the advantages of planned maintenance.
3. describe the planned maintenance process for refrigeration and air-conditioning systems.
4. describe the planned maintenance process for heating systems.
5. list system operational safety concerns that should be addressed on a planned maintenance service call.
6. discuss aspects of planned maintenance that are common to most systems.

90.1 INTRODUCTION

An often repeated bit of folk wisdom is “If it ain’t broke, don’t fix it.” The problem with this philosophy is that it limits service work to emergency operations that are performed under duress after the worst has already happened. It makes life easier to keep things from breaking in the first place.

Planned maintenance enables efficient use of service labor resources. Regular maintenance is scheduled during slow periods, freeing service labor for more emergency service during peak seasons. Scheduling maintenance regularly helps catch small problems before they become big ones, saving both time and money. Keeping systems operating according to manufacturer’s specifications saves both energy and money as well.

90.2 PLANNED MAINTENANCE

Scheduled maintenance calls include four important elements:

1. Routine maintenance on parts that need regular checking, cleaning, or replacing
2. Prestart inspection of the equipment
3. Operation check of the equipment
4. Troubleshooting and correction when necessary

Routine Maintenance

Maintenance schedules are developed according to the season and the system requirements. Seasonal maintenance on heating systems is typically done in the fall, and seasonal maintenance on air-conditioning systems is usually done in the spring. These seasonal checkups are intended to ensure that the systems perform when needed. They are the customer’s insurance policy against system malfunctions during the peak season. However, some system components may need attention more than once a year. Air filters are a good example. Standard 1-in light-duty filters need checking monthly in most houses. The maintenance schedule and services performed will vary depending upon the type of system. What remains constant is that neglecting

the required maintenance will lead to increased operating costs and shorter equipment life.

Prestart Check

There are a few things that need to be checked before starting the system. The best time to discover that the voltage is incorrect is before you start the unit! First find the unit data plate (Figure 90-1) and note all information about the equipment operational requirements. These could include the following:

- The minimum and maximum voltage rating for the equipment
- The current draw of all motors
- The fuel source and fuel pressure for combustion appliances
- The temperature rise for furnaces

Operational Checks

The operation of the equipment should be checked against the manufacturer's specifications. Items to be checked could include the following:

- Operating voltage
- Operating current
- Refrigerant pressures (Figure 90-2)
- Gas manifold pressures
- Temperature rise (Figure 90-3)

90.3 REFRIGERATION/AIR-CONDITIONING MAINTENANCE

Although different types of systems share certain aspects of routine maintenance, each type of system will have areas of maintenance that are vitally important for that type of

system. For air conditioning, all aspects of affecting airflow are crucial to proper system operation.

Routine Maintenance

Air-conditioning and refrigeration equipment should receive an annual checkup and cleaning. This is normally done in the spring. The first order of business is to inspect and clean the coils and filters. The condenser and evaporator should be checked and cleaned if necessary.

Lubrication and Adjustment

Now is a good time to lubricate all bearings and tighten any belts. Most residential blowers use sleeve bearings. Some sleeve bearings require semi-annual lubrication. Many motors have lubrication instructions on the motor (Figure 90-4).

You should only apply oil to oiler tubes. Do not attempt to oil a motor that has no place for adding oil. Do not over-oil; five to ten drops are normally sufficient. Most residential equipment no longer uses belts. If you are working on a piece of equipment with a belt, you should check the belt, the belt alignment, and the belt tension.

Figure 90-3 The temperature rise of gas-fired heating equipment can be found on the unit data plate.**Figure 90-4** The lubricating instructions for this motor are on its data plate.

Figure 90-5 Overheating causes the terminal to discolor and could cause wire insulation to melt.

Figure 90-6 Burned and pitted contactor points, like the ones on the bottom, will create a voltage drop and cause motor overheating.

Prestart Inspection

Check the power supply to the unit with the unit off. It should fall between the minimum and maximum voltage ratings. Visually inspect the wiring for connections that appear discolored. Loose connections create heat, which makes the wires and insulation brittle and burned looking (Figure 90-5).

Inspect the contactor. Its armature should move freely without sticking. The contactor points should be smooth, not pitted. Some discoloration of the points is normal (Figure 90-6).

SERVICE TIP

Do not try to sand or file the points, as you will most likely do more harm than good. Filing removes the silver-cadmium outer plating, which is much more resistant to oxidation than the copper underneath.

Install gauges on the equipment to make sure it has refrigerant. You should not operate equipment without a charge. Check for refrigerant leaks at all mechanical connections and visible brazed joints. Particularly look for signs of oil on the lines or the pipe insulation (Figure 90-7).

If you find leaks, they should be repaired before proceeding.

Operational Checks

Start the system and check the incoming voltage with the unit operating. A significant drop in voltage indicates problems in the power supply. If the voltage drops below the minimum voltage, shut down the system. The contactor contacts should also be checked for voltage drop. The ideal voltage reading from one side of the contact to the other with current going through is 0 V. A reading of more than a few tenths of a volt indicates bad contacts on the contactor. If there is a significant voltage drop across the contacts, shut the system down and change the contactor. A voltage drop across the contactor contacts can kill the compressor.

With the unit operating, check all the following operational characteristics:

- Amp draw of all motors
- Airflow
- Low-side and high-side pressures
- Superheat and subcooling
- Temperature drop across the evaporator

Compare your readings with the manufacturer's specifications.

SERVICE TIP

Most equipment has some operating specifications on the inside of the service panel, including refrigerant charging charts. The electrical specifications can be found on the unit nameplate.

Figure 90-7 Oil is a natural leak indicator; this Vibrasorber has a leak at one end where it flexes.

(Courtesy of HVAC Department, Terra Community College, Fremont, Ohio)

90.4 HEATING SYSTEMS MAINTENANCE

An annual heating system check should include checking the fuel source, performing prestart checks, and checking the air temperature rise. The combustion should be checked on gas and oil furnaces and boilers. See Unit 51 Gas Furnace Installation, and Unit 54 Oil Furnace installation for more details on combustion checks.

90.5 ELECTRIC HEATING

The most important aspects of maintenance for electric furnaces relate to the large amount of electric current they require. Electrical connections are vitally important. Poor connections quickly cause major problems.

Routine Maintenance

The only routine maintenance necessary on an electric furnace would be changing or cleaning the air filter and lubricating the blower. In the rare cases of an electric furnace with a belt-drive blower, you should also check the belt, belt alignment, and belt tension.

Prestart Inspection

The incoming voltage should be checked and compared to the nameplate rating. Perform a visual inspection on all wires and wire connections. Overheating and degradation of wires, wire lugs, and fuse blocks are common problems in electric furnaces. The large current draw turns any small resistance into a small heater that degrades and discolors electrical connections over time. Any visibly discolored wires or wiring components should be replaced.

Operational Check

Checking the power source and all electrical connections is essential when performing annual maintenance. Because electric furnaces use large amounts of power, any resistance in any of the power-handling components leads to heat and failure of that component. More seriously, heated wires, wiring lugs, or fuse blocks can be dangerous.

The voltage to the furnace should be checked before and after starting the furnace. A voltage drop indicates a problem with the power wiring to the furnace. The voltage at the heating elements should be checked and compared to the voltage entering the furnace; they should be the same. A voltage drop indicates that there is a problem in the furnace. This can be located by measuring the voltage across all the power-handling components. An infrared thermometer can also help. The point of voltage drop will be hotter than the rest of the wires and components. The current draw of each heating element should be checked and compared to the nameplate rating. A heat strip that does not draw any current indicates a problem. First check to make sure it has voltage. If no voltage is being applied to the heat strip, the problem is in the controls to that strip. If voltage is being applied and it still has no current draw, then either the heat strip or its fusible link is open. After all heating elements are operating, check the temperature rise of the furnace. Measure the temperature of the air entering

Figure 90-8 These burners are no longer serviceable and should be replaced.

and leaving the furnace. The difference is the temperature rise. The temperature rise should fall within the range listed on the furnace nameplate.

90.6 GAS HEATING

Possibly the most important checks you can perform with a gas furnace is to check for adequate combustion air and proper venting. These are major safety concerns that are easily overlooked if you are focusing solely on the equipment.

Routine Maintenance

As is the case for all forced-air systems, the air filters should be cleaned or changed and the blower motor should be lubricated. For belt-drive systems, the belt, belt alignment, and belt tension should all be checked. Ribbon, slotted, or drilled port burners should be removed so they can be inspected and cleaned. Burners with more than light surface rust should be replaced pending the outcome of the prestart inspection (Figure 90-8).

SERVICE TIP

Loose rust on the burners may not be from the burners but from the heat exchanger. If the burners have large flakes of rust on them, the heat exchanger needs to be carefully checked.

In-shot burners generally do not require cleaning but should be inspected for rust. This can usually be done with an inspection mirror without removing the burners. Extremely rusty burners could indicate a more serious problem that might require replacing the furnace. If you have removed the burners to clean them, leave them out for the prestart check.

On low-NOX furnaces, check the NOX rods or screens for rust, corrosion, or warping. Ribbon burners use rods

Figure 90-9 Deteriorating NOX screen on in-shot burner.

installed over the burner, whereas in-shot burners use screens (Figure 90-9).

SAFETY TIP

Some AQMD (air-quality management districts) require the removal of nitrogen and oxygen compounds (NOX) formed as a byproduct of combustion. Metal rods or screens are placed in the flame to reduce the NOX emissions from the furnace. These rods get red hot and cause a complete burn of the combustion byproducts. Replacing NOX rods that are rusted or corroded is an important safety issue. NOX rods tend to deteriorate, and rust and parts of the rod can fall into ribbon burner slots. Rods have broken, fallen down, and caused fires. They also warp out of their retention brackets and bump into firebox walls. When they go unchecked and warp or rust, they can cause hotspots on the firebox walls, causing cracks and warping of the firebox. They can also restrict gas flow from burners, causing uneven burns or hotspots or premature firebox failure. Routine inspections can ward off issues with these NOX rods.

Prestart Check

The heat exchanger should be visually inspected for holes, cracks, and rust. Some surface rust is normal, but flaky rust that comes off in chunks should be carefully inspected. The heat exchanger may be viewed from the burner end and from the draft diverter end for older-style natural-draft furnaces. An inspection mirror can be helpful, but a flexible fiberoptic or video inspection tool is preferable (Figure 90-10).

SERVICE TIP

On noncondensing furnaces, a better view of the heat exchanger can be gained by removing the blower and looking through the furnace from the blower end. This will not work on condensing furnaces because the recuperative heat exchanger is in the way.

Figure 90-10 This Testo 318 inspection tool can be used to inspect heat exchangers for cracks. (Courtesy of Testo, Inc.)

The heat exchanger will have a separate tube or clam-shell for each burner. Each section needs to be inspected individually.

The vent system should be inspected for loose connections, signs of corrosion, or rust. A rusty or corroded vent indicates condensation in the vent (Figure 90-11).

The cause of the condensation should be determined and corrected. It could be using a single-wall vent in a cold ambient temperature, an oversized vent, a vent with an excessively long horizontal run, a restricted vent, or lack of combustion air. A malfunctioning vent is dangerous; the cause should be found and corrected!

The combustion and venting processes cannot work correctly without adequate combustion and ventilation air. The room the furnace is in should normally be provided with combustion air somewhere near the floor and also near the ceiling. This can be a hole or grille to a ventilated crawlspace or attic or through ducts that go outside. Locate the combustion air openings and verify that they are not blocked (Figure 90-12).

Find the nameplate and write down the following information:

- The type of gas
- The minimum and maximum input gas pressure
- The manifold gas pressure
- The temperature rise
- The operating voltage

Check the incoming gas pressure to see if it falls between the minimum and maximum input pressures. Check the incoming voltage to see if it falls between the minimum and

Figure 90-11 The water in the flue has been condensing in this vent, causing the rust at the joints of the elbow. (Courtesy of HVAC Department, Terra Community College, Fremont, Ohio)

Figure 90-12 Combustion appliances should be supplied with combustion air openings both high and low.

maximum voltage. Install the manometer on the manifold gas pressure port before turning on the system. Any reading other than 0 in wc indicates a leaking gas valve. This is a very rare but dangerous situation. If the gas valve leaks, it must be replaced. Turn off the gas supply and leave the area to let

the accumulated gas dissipate before proceeding. Leave the manometer on for use during the operational check.

SAFETY TIP

Do not put your face directly in front of the burner area when the furnace first lights. Flame rollout and flashback can occur, causing flames to come out from the furnace.

Operational Check

For category I and II furnaces, place a draft gauge in the vent and check the draft with the burners operating. You should have a draft of at least -0.02 in wc. Watch the draft reading when the indoor blower comes on. A reduction in draft or an increase to a positive pressure indicates a leak in the heat exchanger. This is a serious safety issue that generally warrants replacing the furnace.

Check the manifold gas pressure after the burners light. The correct manifold gas pressure at sea level is indicated on the furnace nameplate. The manifold pressure is usually slightly less at higher altitudes. The manufacturer's installation instructions are the best source of information for de-rating gas appliances.

Look at the color of the flames. The flames should be light blue in the center with a darker blue outer area. There should be no yellow. (Figure 90-13).

Figure 90-13 The flame at the top shows a correctly adjusted ribbon burner. The flame on the bottom shows a correctly adjusted in-shot burner.

Figure 90-14 Natural gas flames: (a) correct mixture of fuel and air; (b)-(e) show the effects of decreased primary air. As the primary air is decreased the flame becomes wider and more irregular with a bright yellow color.

Yellow flames indicate incomplete combustion and the presence of carbon monoxide (Figure 90-14).

Yellow flames are the result of too much gas, too little air, or faulty burners. Older gas furnaces have adjustable primary air intakes (Figure 90-15).

The primary air can be adjusted until the yellow disappears. However, opening the shutters too far can cause delayed ignition, especially on cold days. Too much primary air also causes the flames to lift away from the burner face.

Figure 90-15 Some gas burners have primary air shutters for adjusting the amount of primary air to the burner.

In-shot burners, like those in most modern furnaces, do not have any primary air adjustment. Yellow flames on these furnaces indicate a lack of combustion air in the room or too much gas. Check the orifice size against the manufacturer's specifications or an orifice chart to make certain the furnace has the correct size of gas orifices (Figure 90-16 and 90-17).

The combustion gases in the vent should be checked for carbon monoxide. Ideally, the carbon monoxide level

Figure 90-16 The orifice size is stamped on it; this is a #43.

ORIFICE SIZE FOR 23,000 BTUH GAS FIRED BURNER					
Altitude	0 – 7,000	7,001 – 11,000	0 – 7,000	7,001 – 9,000	9,001 – 11,000
Type of Gas	LP	LP	Natural	Natural	Natural
Orifice Size	#55	#56	#43	#44	#45

Figure 90-17 The same furnace may require four different orifices depending upon the type of gas and altitude.

Figure 90-18 Carbon monoxide testers can read the level of CO in the flue gas.

should be 0 ppm for complete combustion. Realistically, it is common for some low level of CO to be present in the combustion gases. Levels of CO in the vent gases exceeding 50 parts per million warrant a closer look at the combustion process (Figure 90-18).

After the blower has been operating for a few minutes, check the temperature of the air entering and leaving the furnace. The difference is the temperature rise (Figure 90-19).

Be sure to check the leaving-air temperature in a location that is not directly in the line of sight of the heat exchanger. If the thermometer can “see” the heat exchanger, it may read higher due to the heat exchanger’s radiant heat. If the temperature rise is too high, the airflow needs to be increased. If the temperature rise is too low, the airflow needs to be reduced.

Figure 90-19 Temperature rise is the difference between supply- and return-air temperatures.

90.7 OIL-FIRED HEATING

As with gas furnaces, combustion air and venting are major safety concerns. Annual maintenance is a requirement to keep oil-fired equipment operating properly. Measuring and adjusting the burner to produce proper flame and combustion gas characteristics should be performed annually.

Routine Maintenance

Like all forced-air systems, the air filters should be cleaned or changed and the blower motor should be lubricated. For belt-drive systems, the belt, belt alignment, and belt tension should all be checked. Items unique to oil furnaces include changing the fuel oil filter, replacing the nozzle, lubricating the oil burner motor, inspecting the drive coupling, and inspecting the combustion chamber. All of these items should be done once a year. The fuel oil filter should be changed every time the oil tank is refilled but no less than once a year.

Prestart Check

The oil burner will have to be removed to perform the annual maintenance and preseason check. After removing the oil burner, you should:

- Change the nozzle. Make sure to replace it with the same spray pattern and angle (Figure 90-20).
- Inspect the electrodes for cracks in the ceramic insulators (Figure 90-21).

Figure 90-20 (a) Nozzle, electrodes, and air; (b) various sizes and types of nozzles; (see next page) (c) nozzle size is stamped on the nozzle; (d) nozzle angle is stamped on the nozzle.

(c)

(d)

Figure 90-20 (Continued)

Figure 90-21 Cracks in the electrode porcelain can allow spark to arc at unwanted places and reduce the arc available at the electrode tip. (Courtesy of HVAC Department, Terra Community College, Fremont, Ohio)

- Clean the electrodes and set them to the correct angle and gap (Figure 90-22).
- Adjust the Z dimension of the burner tube (Figure 90-23).
- Inspect the drive coupling (Figure 90-24).
- Clean the cad cell sensor (Figure 90-25).

While the burner is removed, clean any accumulated debris out of the combustion chamber and inspect the combustion chamber liner. If it has deteriorated, it should be replaced. Replace the burner after these steps are completed.

Figure 90-22 Electrode-spacing dimensions for an oil burner.

Figure 90-23 The "Z dimension" is the distance from the tip of the nozzle to the face on the burner head; an incorrect setting can cause incomplete combustion.

SAFETY TIP

If the burner has not been firing, a dangerous accumulation of oil in the combustion chamber can result from pushing the reset button several times. The customer may have tried resetting the burner several times before calling for service. This oil needs to be cleaned from the combustion chamber as thoroughly as possible. Lighting the furnace with a soaked combustion chamber may lead to an explosion!

Figure 90-24 The drive coupling makes the connection between the oil pump motor and the oil pump. (Courtesy of HVAC Department, Terra Community College, Fremont, Ohio)

Figure 90-25 Accumulated dirt and soot on the cad cell can keep it from seeing the flames. (Courtesy of HVAC Department, Terra Community College, Fremont, Ohio)

The vent system should be inspected for loose connections, signs of corrosion, and rust. The barometric damper should move freely (Figure 90-26).

Look to make sure adequate combustion air is provided. Find the nameplate and write down the temperature rise and the minimum and maximum operating voltages. Check the incoming voltage to see if it falls between the minimum and maximum voltage.

Figure 90-26 The barometric damper maintains the correct over-fire draft in an oil furnace. (Courtesy of HVAC Department, Terra Community College, Fremont, Ohio)

Operational Check

To correctly adjust the burner, it will be necessary to measure the oil pump pressure, stack temperature, and carbon dioxide flue gas percentage. Install a pressure gauge on the pressure port of the oil pump (Figure 90-27).

Look in the manufacturer's literature or on the oil burner for the correct pump pressure. The most common pressure has been 100 psig for many years. However, most recent oil burners operate at higher pressures—140–170 psig. Start

Figure 90-27 This fuel oil test kit can be used to check the operation oil pump pressure. (Courtesy of Ritchie Engineering Company, Inc., Yellow Jacket Products Division)

Figure 90-28 The oil pressure is increased by turning the adjusting screw clockwise and decreased by turning it counterclockwise. (Courtesy of HVAC Department, Terra Community College, Fremont, Ohio)

the burner and compare the oil pump pressure to the recommended pressure. If the pressure is not correct, turn the adjusting screw clockwise to increase pressure or counterclockwise to decrease pressure (Figure 90-28).

The operation of the barometric damper should be checked. The manufacturer's instructions should list the recommended draft pressure between the damper and the furnace: -0.02 in wc is common. Adjust the weight on the barometric damper to achieve the correct draft.

Measure the smoke spot and the CO_2 percentage. The correct flame should have no smoke and a CO_2 level between 10 and 12.5 percent. If there is smoke in the flame or if the CO_2 level is outside of the 10 to 12.5 percent range, you need to adjust the air. To do this, follow these steps:

1. Adjust the air inlet vane until you see a trace of smoke in the flame.
2. Measure the CO_2 content of the flue gas.
3. Open the air until you have lowered the CO_2 by 1 or 2 percent.
4. The correct flame should have no smoke and CO_2 between 10 and 12.5 percent.

Ideally, the combustion efficiency should be measured and the flue gas should be checked for carbon monoxide. Measure the stack temperature and subtract the equipment ambient temperature from it to get the net stack temperature. The combustion efficiency can be calculated using the CO_2 percentage, the net stack temperature, and a combustion efficiency slide rule. The flue gas should have no carbon monoxide, but trace amounts of up to 50 ppm are acceptable. Check the temperature rise and blower current draw once the indoor blower comes on.

90.8 HYDRONIC HEATING

One advantage of hydronic heating systems is their low maintenance requirements. Maintenance can be divided into three general areas:

Figure 90-29 The temperature- and pressure-relief valve is an extremely important safety item; it opens to relieve excessive pressure, preventing boiler explosion.

- Boiler
- Pump and controls
- Piping, radiators, and convectors

Hydronic boilers do not really boil the water; they are more like efficient hot-water heaters for nonpotable water. The temperature-pressure relief valve should be checked annually (Figure 90-29).

Pull the lever on top of the valve and water should come out the discharge pipe connected to the temperature-pressure valve. Take caution, because this releases scalding hot water under pressure. Keep away from the discharge outlet and do not stand directly in front of the valve. The remaining maintenance requirements vary depending upon the fuel the boiler uses. They can operate on electricity, fuel oil, or gas.

Electric Boilers

Electric boilers require the least amount of maintenance because there is no combustion process. Because they use large amounts of current, the power source, all controls, and connections should be checked annually. Visually check for overheated wires and wire connections. Measure the element voltage and compare it to the nameplate voltage and the actual incoming voltage. Any voltage drop in the circuitry or controls should be located and eliminated. Finally, the current draw of each element should be checked against the nameplate rating.

Gas-Fired and Oil-Fired Boilers

Gas-fired and oil-fired boilers should have their combustion air, combustion process, and vent system checked. These checks are similar to the checks used on gas and oil furnaces.

Water Pump

A water pump is used in hydronic heating systems to circulate the hot water. The vast majority of the pumps used today in residential systems are maintenance free. They

Figure 90-30 This system's water flow can easily be checked by looking at this water flow meter.

have no seals to leak and they are typically cooled and lubricated by the water they pump. Checking the water pump consists of checking the amount of water it is pumping. This is done two ways. Some systems have water flow indicators that visually show the rate of water flow (Figure 90-30). Unfortunately, many systems do not have a water flow indicator. The other common method of checking the water flow is to measure the pressure drop across the pump and compare it to the pump specifications. This is quite accurate but requires the pump specifications.

Piping and Fluid

The system should be inspected for water leaks. Systems that use a lot of makeup water have leaks. The system water pressure should also be checked (Figure 90-31).

Most hydronic systems should be kept at a pressure of 10 to 20 psig. Below 10 psig, systems experience more problems with air entrainment and corrosion. The pressure-relief valve on most residential boilers opens at 30 psig, so the loop pressure should be kept enough below 30 psig to prevent opening the pressure-relief valve.

Most hydronic systems are closed loops and use glycols and corrosion inhibitors in the water. The water pH level should be checked to ensure it is not corrosive to the system piping and components. This can be done with a pH meter (Figure 90-32).

Generally, the pH should be between 8.5 and 10.5. The fluid's pH drops as the inhibitors wear. Adding inhibitor increases the water pH level. Check with the boiler manufacturer for the correct glycol and inhibitor solutions for the system.

TECH TIP

Generally speaking, it is not a good idea to use automotive antifreeze. The inhibitors added are specific to the types of materials in the system. Because automobile engines contain different materials than hydronic heating systems, the antifreeze formulation is different.

Figure 90-31 This pressure gauge shows the pressure in the water loop.

Figure 90-32 A pH meter like this one can be used to check the water pH. (Courtesy of Extech Instruments, A FLIR Company)

90.9 HEAT PUMPS

During a heat pump planned service call, the cooling, heating, defrost, auxiliary heat, and emergency heat cycles should all be checked whenever possible. However, most air source heat pump systems should not be operated in the cooling cycle at temperatures below 50°F or in the heating and defrost cycles at temperatures above 70°F.

Cooling Cycle

In cooling, heat pumps are functionally very similar to air-conditioning systems. Checking a heat pump in the cooling cycle is essentially the same as checking an air-conditioning system.

Heating Cycle

The routine maintenance for the heating cycle is also similar to air conditioning:

- Clean or change the air filter.
- Clean the outdoor coil.
- Check the indoor coil.
- Lubricate the motors.

The operational check should include the following:

- Amp draw of all motors
- Airflow
- Low-side and high-side pressures
- Superheat and subcooling
- Temperature rise across the indoor coil

Determining the correct charge in the heating cycle can be tricky because the system capacity varies with the operating conditions. Typically the heating capacity of most air-source heat pumps at 45°F is similar to their cooling capacity at 95°F. But their heating capacity at 17°F is just a little more than half that. There is also about half the amount of refrigerant circulating. Manufacturers have different ways of handling this. It is essential that the equipment manufacturer's charge-checking method be used for accurate results. The most common methods of checking the heating cycle operation are as follows:

- Temperature rise across the indoor coil
- Pressure-temperature charts (Figure 90-33)

HEATING CHECK CHART FOR R-22 AIR SOURCE HEAT PUMP								
INDOOR TEMPERATURE	PRESSURE	OUTDOOR TEMPERATURE						
		60°F	50°F	40°F	30°F	20°F	10°F	0°F
60°F	HIGH	217	201	186	170	154	139	123
	LOW	68	50	41	53	35	27	17
70°F	HIGH	248	230	213	195	178	161	143
	LOW	71	62	53	44	36	27	17
80°F	HIGH	279	260	241	222	203	185	166
	LOW	74	65	55	46	36	27	17

USE OF CHART
Table indicates whether a correct relationship exists between system operating pressure and air temperature entering indoor and outdoor units. If pressure and temperature do not match on chart, system refrigerant charge may not be correct or other system abnormalities may exist. Do not use table to adjust refrigerant charge.

CHARGING
When charging is necessary during heating season, remove any refrigerant remaining in system, evacuate and recharge by weight. Weigh in total charge as indicated on unit rating plate. Rating plate charge is for systems with 15 ft. line-set. Adjust charge at rate of 0.6 oz/ft of 3/8" liquid line over 15 ft.

Figure 90-33 A check chart is used to check the heating operation, but it is not used for adjusting the charge.

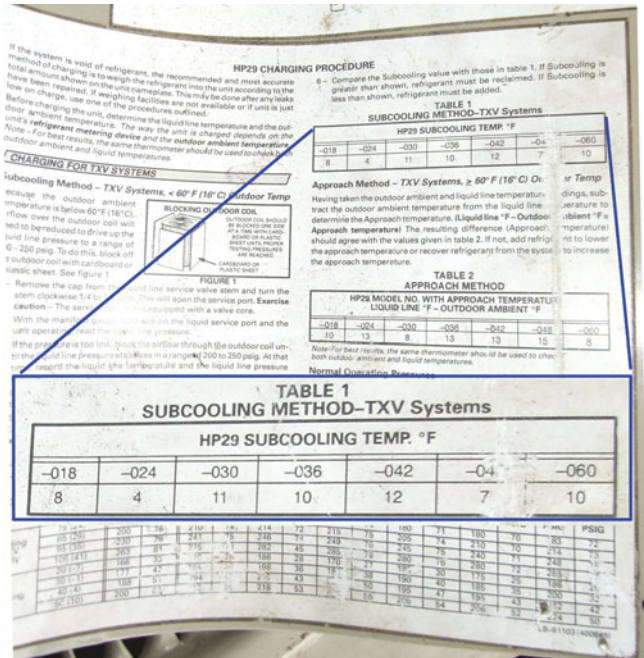

Figure 90-34 The charge may be checked using subcooling when the temperature is below 60°F; operate the unit in cooling and block the condenser to raise the liquid pressure to 200–250 psig (R-22).

- Subcooling (Figure 90-34)
- Ambient temperature approach (Figure 90-35)
- Suction superheat (Figure 90-36)
- Discharge line temperature

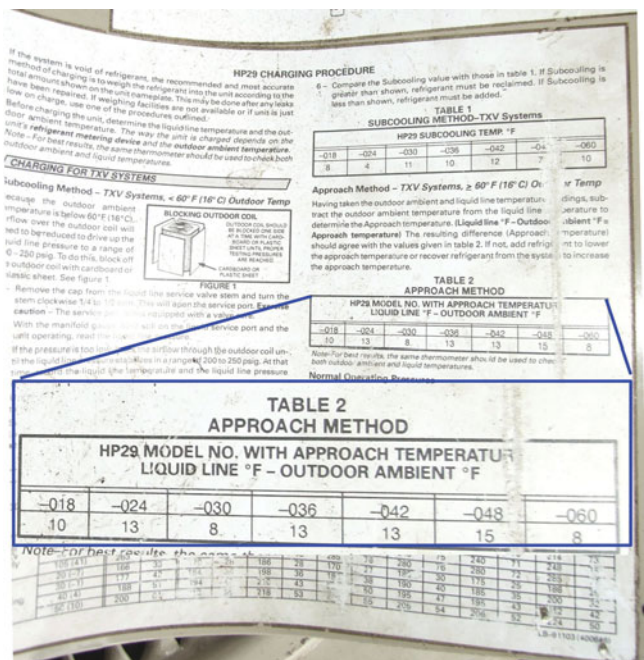

Figure 90-35 The approach method compares the outdoor temperature to the liquid-line temperature while operating in cooling; the ambient temperature must be above 60°F.

Figure 90-36 This chart gives the system’s suction superheat in the heating cycle.

Superheat at Compressor Suction in Heating Operation

Indoor Temperature	Outdoor Ambient Temperature							
	-10°F	0°F	10°F	20°F	30°F	40°F	50°F	60°F
55°F	NR	6	8	10	13	20	27	37
70°F	NR	NR	NR	NR	5	12	20	30
80°F	NR	NR	NR	NR	NR	8	16	26

Note: Chart values assume design airflow over both indoor and outdoor units

Table 90-1 Outdoor Temperature

	0°F	10°F	20°F	30°F	40°F	50°F
Temperature rise	9	11	14	18	23	28
Percent nominal capacity	33%	40%	50%	65%	82%	100%

The temperature-rise method can be applied to any unit if you know the indoor airflow and the specified system BTU/hr capacity at the current outdoor temperature. The expected temperature rise can be calculated using the formula

Temp rise = Btu/(CFM × 1.08)

The chart in Table 90-1 shows a calculated temperature rise for single-speed systems whose airflow is 400 CFM per ton. The percentage capacity used for the calculations is shown in Table 90-1.

Some manufacturers provide charts for checking the heating cycle. These are used to check the system pressures at specific operating conditions but are not intended for use in charging systems. This is because it is possible to have enough refrigerant in the system to operate correctly at 25°F and still be undercharged at 45°. Typically these charts give you an expected high- and low-side pressure range for specific outdoor ambient temperatures.

The discharge-line temperature method is used by one major manufacturer. It compares the discharge-line temperature to the outdoor temperature. The discharge-line temperature should be 110°F hotter than the outdoor ambient temperature. For example, a system operating in a 40°F ambient should have a discharge-line temperature of 150°F: 40°F + 110°F = 150°F.

90.10 COIL MAINTENANCE

Condenser coils and evaporator coils are designed to exchange heat between the refrigerant in the coil and the air passing over the coil. Dirty coils cannot perform their function because the dirt adds resistance to airflow, reducing the amount of air passing over the coil. The dirt also acts as an insulator, slowing the transfer of heat between the refrigerant and the air.

Figure 90-37 Dirty air-cooled condensers are a common problem.

Air-Cooled Condensers

Dirty condenser coils restrict airflow, raise the condenser temperature and pressure, reduce efficiency, and shorten equipment life (Figure 90-37). Air-cooled condensers should be cleaned annually regardless of how clean they appear. A coil that appears clean can have dirt packed inside the fins where you cannot see.

Always follow the equipment manufacturer’s recommendations when selecting cleaning agents. Cleaning with the wrong chemicals or applying the chemicals incorrectly can do more harm than good. In particular, check that you have properly diluted the coil cleaner (Figure 90-38).

Before cleaning the coil, turn the power to the unit off and check it with a meter to ensure that it is off. Remove matted material with a stiff brush. Apply coil cleaner according

Figure 90-38 Make sure to dilute coil cleaner according to the manufacturer's directions.

to the chemical manufacturer's instructions. Rinse going in the opposite direction of air flow to help with the removal of pet hair and material caught between the fins. Material can get caught between the coils on some double-row coils. If possible, separate the two coils to remove the trapped material. Debris can also get caught between the coil and the metal louvered coil guards on some units. Removal of the metal panels may be necessary to get this material out.

Many types of coil cleaner are sold concentrated and must be diluted with water before using. Care should be taken to rinse the coils thoroughly so that no cleaning chemicals remain on the coil. For spiny-fin coils that have the fins wrapped around the tubes, the amount of pressure used to apply both the cleaner and the water needs to be very low. These fins are quite thin and will crush easily. Flattening the fins essentially does the same thing as having them matted with dirt; the airflow is restricted (Figure 90-39). These coils cannot be straightened with a fin comb, so damaged coils are nearly impossible to repair.

Figure 90-39 Be careful when cleaning spiny fins; they can be easily crushed.

Figure 90-40 Dirty evaporators are a common problem that is often misdiagnosed as a refrigerant undercharge. (Courtesy of Nu-Calgon)

Air-Conditioning Evaporator Coils

Air-conditioning evaporator coils should be protected by an air filter. You should always clean or replace the indoor air filter when servicing an air conditioner. If this filter is cleaned or changed regularly, then the evaporator will usually stay clean. If possible, you should visually inspect the evaporator to make certain that it is clean, but it is not necessary to clean the evaporator every year. However, if the filters are not kept clean, the evaporator can become matted with dirt (Figure 90-40).

Since the evaporator is usually wet when it runs, dirt sticks to it. In severe cases, this can reduce the airflow to the point that the evaporator freezes up. A frozen coil can be spotted by the ice around the suction line leaving the coil. If the unit runs long enough with a frozen evaporator, the suction line will freeze all the way back to the compressor (Figure 90-41).

The side of the coil that needs cleaning is where the air enters the coil. After removing the access door on an evaporator casing, what is usually visible is the side of the coil where the air leaves. You may have to remove interior sheet metal, cut into ductwork, or even entirely remove the evaporator coil to gain access to the side that needs cleaning (Figure 90-42).

Obviously it is easier to keep the coil clean in the first place! Another complication when cleaning evaporator coils is controlling the mess that is made. Condensers are usually outside, so the resulting mess is not as critical. But evaporators are normally inside, and it just is not feasible to wash it down with a garden hose. Some cleaners are designed to be rinsed by the water that condenses on the evaporator as it operates. However, you should check with the equipment manufacturer before using them. A hand pump chemical sprayer is a practical way to apply coil cleaner and control the amount and direction of the water spray when rinsing the coil.

Figure 90-41 If a unit continues to operate after the evaporator coil freezes, the ice will travel down the suction line and even up onto the compressor. (Courtesy of HVAC Department, Terra Community College, Fremont, Ohio)

Figure 90-42 The triangle endplate must be removed from the coil to gain access to the underside of the coil where dirt collects.

To clean the evaporator coil, you should do the following:

1. Remove any visible dirt accumulation with a stiff brush.
2. Clean out the drain and drain pan. A free-flowing drain will make the rest of the job easier.
3. Apply a properly diluted coil cleaner to both sides of the coil.
4. Thoroughly rinse the coil starting from the leaving-air side. This will help push wedged debris out.

There are methods for cleaning the coil from the leaving-air side. But without seeing the results, you cannot be certain you have properly completed the job. These methods include high-pressure air to blow backwards through the coil and chemical foams that are applied to the leaving-air side. One problem with blowing the dirt off and leaving it is that the dirt is still there and could become trapped in the coil again. The foam cleaner works by expanding and pushing the dirt out the other way. The water condensing on the coil when the unit operates is then supposed to rinse off the foam.

Even though the evaporator coil does not always need cleaning, the drain pan and drain line usually do. The quickest and most effective way to clean a drain pan and drain is with a tool that uses air pressure or nitrogen pressure to create suction. This lets you suck the water and slime out of the drain pan and drain (Figure 90-43).

Figure 90-43 A sludge sucker can be used to clear a drain line from the outside. (Courtesy of Uniweld Products, Inc.)

Figure 90-44 Example of mineral deposits on an ice machine water float.

Water Coils

Systems that have water circulating in open loops should have the water checked weekly. Any water that is open to the air will grow things.

From ice machines to high-temperature water-jacketed heat exchangers, if the water is open to the air, something will grow in the water. Evaporation of water in open-loop systems leads to increased mineral concentration in the water. This leads to salting or calcification of all the water-handling parts (Figure 90-44).

This can be controlled with regular maintenance. Regular maintenance on the water side of systems typically consists of testing the water and adding chemicals as needed to prevent biological fouling and mineral scaling. Regular cleaning is necessary for systems such as ice machines where chemicals cannot be present in the water during normal operation. Most ice machines should be cleaned monthly.

90.11 MAINTENANCE OF ELECTRONIC AIR FILTERS

Service on electronic air cleaners consists of the following steps:

1. Inspecting the air cleaner cells
2. Checking the operation of the air cleaner
3. Cleaning the prefilter
4. Cleaning the collector plates

Inspection

Turn off the power to the air cleaner. Normally there is a switch on the door or on top of the air cleaner. Most air cleaners have power indicator lights that will show when power is on. Remove the access door on the side of the air cleaner. The cells will slide out. Typically there will be one or two cells. Pay careful attention to how the cells are oriented so that you can reinsert them correctly. Many have arrows showing the direction of airflow or keyways to prevent misalignment (Figure 90-45).

Figure 90-45 The arrow on the side of the air cleaner cell indicates the airflow direction.

Visually check the fine wires on the front of the cells. There should be no loose wires. Reinsert the cells for the operational check.

Operational Check

Many electronic air cleaners have test buttons and/or test lights to indicate that the air cleaner is operating correctly. The test lights are wired to a transformer and tuned circuit in the air cleaner. They light when the air cleaner power supply is operating correctly (Figure 90-46).

Figure 90-46 The light at the top right is lit to indicate that the air cleaner is energized. (Courtesy of HVAC Department, Terra Community College, Fremont, Ohio)

Figure 90-47 Pushing the test button at the bottom produces a snapping sound to indicate that the air cleaner is working.
(Courtesy of HVAC Department, Terra Community College, Fremont, Ohio)

The test button temporarily shorts across the positive and negative plates. This causes a loud zapping noise that indicates the air cleaner is working (Figure 90-47).

Do not try to short across the plates with anything else. The plates have 8,000 V dc on them, and touching them during operation would literally be a shocking experience!

Some air cleaners have circuits that detect airflow and automatically energize the cells when airflow is detected. These usually have lights indicating when airflow is detected (Figure 90-48).

Make sure that the light comes on when the fan comes on and goes off when the fan goes off. These circuits are a common source of problems. If the circuit does not work, check to see that the air sensor tube is not plugged with debris (Figure 90-49).

Prefilter Cleaning

The prefilter is similar to a cleanable 1-in low-efficiency air filter. Its job is to collect large dust particles and keep them out of the collector plates. When a large particle does occasionally make it into the air cleaner, you will hear a loud

Figure 90-48 The green light on this air cleaner lights up whenever the air cleaner detects airflow and turns itself on.

Figure 90-49 This sensor energizes the air cleaner whenever it senses airflow.

zapping noise similar to a bug zapper. The prefilter should be cleaned monthly.

Cleaning the Air-Cleaner Cells

The air-cleaner cells should be cleaned once a year. They can be cleaned in a dishwasher, or they can be cleaned with coil cleaner and rinsed. They should be allowed to dry before being placed back into the air cleaner. It would not be good to apply 8,000 V to a dripping-wet metal appliance.

90.12 AIR FILTERS

Air filters for residential systems are available in sizes from 1–5 in, in efficiencies from MERV 1 to MERV 12, and can be disposable or cleanable. The least expensive low-efficiency filters are intended to protect your equipment, while the higher-efficiency filters are intended to protect the equipment and clean the air.

Disposable 1-in Filters

Most 1-in filters should be changed monthly, including the standard 1-in disposable air filter. Disposable 1-in filters come in several efficiencies. As consumers become more concerned with indoor air quality, high-efficiency pleated 1-in filters are growing in popularity. Unfortunately, the higher efficiency 1-in disposable filters have a very high pressure drop, even when clean. The system airflow should be checked if lower-efficiency 1-in filters are replaced with higher-efficiency 1-in filters. It is essential that these filters be changed monthly. The cost of changing the filter monthly is far less than the cost of the extra energy consumed as a result of operating a system with dirty filters. In a worst-case scenario, dirty air filters can lead to blocked indoor air coils and dead compressors. The cost of replacing a dead compressor will exceed the cost of replacing filters monthly for several years.

Pay attention to the directional arrows on the filter when inserting one. The arrows point in the direction of airflow. This should be toward the unit (Figure 90-50).

Figure 90-50 Filters have arrows on the sides to indicate the direction of airflow.

Cleanable 1-in Filters

Most cleanable filters are 1 in thick. Cleanable low-efficiency filters include hog's hair, expanded metal, and foam. These should be cleaned monthly. They may require more frequent cleaning in abnormally dirty conditions. Rinsing with water and mild detergent works well for these. Electrostatic air filters are a type of cleanable medium-efficiency 1-in filters. These use materials that build up a static charge as air passes over them. Keeping these filters clean is critical. They have a higher pressure drop than standard air filters when they are clean. When they are dirty, they restrict airflow to the point that most of them will not operate correctly. They are also very difficult to clean when they have become packed with dirt. These should be cleaned monthly.

High-Efficiency Pleated Filters

Pleated disposable filters are available in 4-in and 5-in widths (Figure 90-51). These filters have MERV ratings from 8 to 12. The pleats provide more surface area for the air to pass through, so the filters can use a denser material. This allows higher-efficiency filtering without imposing large pressure drops. However, they do have a higher pressure drop than low-efficiency 1-in filters. Large pleated filters have the added benefit of lasting longer between filter changes. Pleated high-efficiency 5-in filters normally

Figure 90-51 The combs in this filter separate the pleats; they must be removed and reinstalled when changing the filter media.

only need to be changed every 6 months. Some may go as long as a year depending upon the amount of material in the air. Two types are available: accordion-fold filters that are assembled in the field and box filters that have a cardboard support around the pleats. The field-assembled filters typically have combs that separate and support the pleats. Assembling these can be tricky if you have not done it before. Pay attention to the way the parts fit together when disassembling the old filter so that you will know how to reassemble the new one. Make certain the arrows indicating the airflow are facing the correct direction.

90.13 BELT-DRIVE ASSEMBLY CHECKING

Belt-drive assemblies are used to drive fans and compressors in commercial equipment. Some older residential equipment used belt-drive fans, but residential equipment built after 1970 is all direct drive. When checking a belt-drive assembly, you should check the following:

- Shaft alignment
- Pulley alignment
- Pulley wear
- Shaft bearings
- Belt tension
- Belt condition

Safety

All work on belt-drive systems should be done with the system off and locked out. You should never try to adjust a belt-drive system with the power on. An unexpected system start-up could cause severe personal injury.

Shaft Alignment

The drive shaft and the driven shaft should be parallel in two axes. This can be checked by viewing the shafts from above and from the side. The shaft centers should be the same distance apart at the front and back of the shaft. Typically, the motor mounts are adjustable, and any shaft misalignment is corrected through adjustments to the motor mount (Figure 90-52).

Pulley Alignment

The two pulleys should be in line so that a straight edge will lay flat across the outside face of both pulleys (Figure 90-53). The pulley alignment can also be checked by looking at how the belt leaves the pulleys. If the belt appears to veer to the right or left after leaving the pulley, the pulleys are not properly aligned (Figure 90-54). This can be corrected by loosening the setscrew on the pulley and moving it until the belt comes off the pulley in a straight line.

Pulley Wear

Improper belt tension and misaligned belts both can cause excessive wear on aluminum pulleys. Pulleys that are cupped or grooved on the inside should be replaced.

Shaft Bearings

Belt-driven devices have bearings that should be checked and lubricated. Belt-drive fans typically use pillow-block

Figure 90-52 These shafts are not in alignment; the straight edge does not rest straight across the faces of the pulleys.

Figure 90-53 These shafts are in alignment; the straight edge rests flat against the faces of the pulleys.

Figure 90-54 These pulleys are out of alignment; the belt is pulling to the left.

bearings that are lubricated with a small amount of grease added through the grease fittings using a grease gun.

Belt Tension

The correct tension for any belt-drive application is the minimum tension required to keep the belt from slipping at its maximum torque. For blowers, this is at start-up. Belt manufacturers publish specifications for the design load of their belts, but a belt may not be operating at its maximum design load on any particular application. Tensioning a belt past the required torque can actually shorten its life. If a fan belt does not slip on start-up, it is tight enough.

Belt-drive blowers typically use V-belts. New V-belts need to operate a while to settle in. They need to be re-tensioned after the first several hours of operation. This requires going back to the job to re-tension the belt. Some belt manufacturers specify different tensions for new belts and old belts. The new belt tension is higher to allow for the belt settling in. The intent is to avoid going back to re-tension the belt. Belt tensions should be checked every 6 months. There is no single tension specification that is accurate for all belts. The most common method is to check deflection of the belt while applying force to the center of the belt span (Figure 90-55).

The amount of force and amount of deflection differ from belt to belt. Belt manufacturers publish charts showing the proper amount of force and deflection for any given belt. In general, longer belts will have more deflection than shorter belts.

Belt Condition

Belts wear out. They wear out more quickly if the alignment and tension are not correct, but even if all drive components are properly aligned and the belt is properly tensioned, it will still wear out. Worn belts will have one or more of the following characteristics:

- Hard and glazed sides (Figure 90-56).
- Dried and cracked, not soft and pliable
- Deformed sides
- Frayed

Belt Replacement

Most belts will last for several years. When it is time to install a new belt it is important to do it correctly. A common but incorrect method of installing a belt is to roll it over the outside edge of the pulley (Figure 90-57). This can damage the belt and shorten its life. The belt tension adjustment should

Figure 90-55 Belt-tension gauges measure the amount of force required to produce belt deflection.

Figure 90-56 The sides of this belt are shiny and glazed; this belt needs replacing.

Figure 90-57 Belts should *not* be installed by rolling them over the pulley.

be loosened until the belt fits easily over the pulley and then retightened after installing the belt. Be sure to check the pulley alignment and belt tension after installing a new belt.

Common Problems and Misconceptions

A sure sign of a belt-drive problem is vibration. Belt vibrations are caused by alignment problems or hardware problems. If the pulleys are misaligned, the belt has to jump over the side of the pulley, causing vibrations. Warped pulleys or shafts can do the same thing. This problem is frequently mistaken as a sign of a loose belt. Tightening the belt reduces the size of the arc in the belt vibration but does not solve the problem. In fact, tightening a belt that is oscillating may actually increase belt wear.

Loose belts slip, causing a squealing noise. The proper fix is to ensure proper alignment and tighten the belt. Unfortunately, a common “remedy” is lubricating the belt or treating it with belt dressing sprays. These only fix the sound. The lubricated belt slips even more, but it does so quietly—and usually just long enough for the technician to leave. Belt dress-

ings are designed to make the belt tacky and reduce slippage. However, that is also short lived. If the belt is loose it should be tightened; if it has glazed walls it should be replaced.

90.14 SOUND-LEVEL MONITORING

Sound-level monitoring is one technique used for predictive maintenance. The goal of predictive maintenance is to monitor system behavior, document changes in behavior, and repair or replace components that are on a predictable path toward failure. Machines all have their own sounds. When these sounds change, something has changed about the machine. Ultrasonic sound-level meters can be used to hear sounds outside of human hearing. Increased friction leads to increased sound. When a machine changes its tune, it is trying to tell you something.

Dosimeters are used to measure ultrasonic sound levels. They measure ultrasound in decibels relative to 1 millivolt, abbreviated dBmv (Figure 90-58). The ultrasonic output

Figure 90-58 Noise dosimeter with data logger.

Figure 90-59 The sleeve bearing is shown highlighted in blue.

of a bearing should be relatively constant at $\pm 3\text{--}4$ dBmv. Small increases in ultrasonic output indicate the need for bearing lubrication. Larger increases warn of the earliest stages of bearing failure.

90.15 LUBRICATION

There is really not a lot to lubricate on most modern heating and air-conditioning systems. Only the fan motors need lubricating on most systems. Even many fan motors are now using sealed bearings that cannot be lubricated. Two types of bearings are used: ball bearings and sleeve bearings. Most residential applications use sleeve bearings.

Sleeve bearings are metal bushings whose inside diameter is just a few thousandths of an inch larger than the shaft diameter (Figure 90-59). An oil film separates the shaft from the bearing, and the shaft hydroplanes on the bearing. The shaft does not touch the bearing when it is operating. In small motors, a packing around the bearing holds oil like a sponge and releases it as the bearing heats up.

A slice is taken out of part of the bearing to allow the oil to reach the inside bearing surface (Figure 90-60). This

Figure 90-60 The slice at the top of the sleeve bearing allows oil to feed into the area between the shaft and the bearing.

Figure 90-61 These oiler tubes carry oil to the packing around the sleeve bearing.

type of bearing is oiled through the oiler ports on the motor (Figure 90-61). Ideally, these should be pointing up, but they are sometimes on the side coming off at an angle. They should never be pointing down. Many motors have lubrication instructions on them. Typically they use 5–10 drops of SAE 10 to 20 weight oil. Never use penetrating oils or spray lubricants. They are too thin and the solvents in them can attack the materials in the motor. The time period before the first lubrication is normally longer than subsequent lubrications. The initial operating period before lubrication is often as long as 2 years. The time between normal lubrications varies from 3 months to a year.

TECH TIP

Do not attempt to oil any part of an electric motor other than at the oiler holes. Spraying oil all around the motor will just accumulate dust faster and contribute to winding breakdown.

Larger motors typically use ball bearings or roller bearings. These are lubricated with grease. The grease should create a film over all the bearing components. It should not fill up all the space in the bearing (Figure 90-62). If the bearing is completely filled with grease, the balls have to push through it. This actually increases the bearing temperature.

Figure 90-62 A properly lubricated ball bearing should not have grease packed in every space between the ball bearings but just around the races.

Figure 90-63 Many large motors have grease ports for greasing the bearings.

Further, the grease is whipped up and loses some of its ability to lubricate. Expansion of excess grease will force open the seals in the bearings and destroy the bearing. To lubricate a bearing with grease fittings you should follow these steps:

1. Open both the fill and drain ports (Figure 90-63).
2. Operate the motor until the bearing is warm.
3. Add the manufacturer recommended amount of grease in the fill port.
4. Operate the motor with the ports still open until the bearing is warm.
5. Replace the port plugs.

If the manufacturer's recommendations are not available, use an ultrasonic tester to listen to the bearing and add small amounts until the bearing noise abates.

SERVICE TIP

A common misconception is that grease should be added until all the old grease is purged and new grease starts to exit the drain port. This will certainly fill all the bearing cavities with grease; thus this procedure is guaranteed to over-grease the bearing and shorten its life.

90.16 VISUAL INSPECTION

Your eyes are one of the most powerful tools at your disposal when performing routine inspections. Many system problems give visual clues about a system's operation. Take some time at the beginning to look the system over carefully. Oil spots on refrigerant lines indicate leaks. Stains on gas vents indicate venting problems. Darkened

or discolored wires have been overheated. Corroded electrical connections indicate loose connections. System installation errors can often be readily seen. A few items to look for would be the following:

- Combustion air grilles in the case of gas and oil appliances
- Mechanical components properly supported
- Ductwork insulated
- Suction line insulated
- Service clearance in front of unit
- Drains running downhill

90.17 CALIBRATION

To calibrate a control, compare its output to an accepted standard and adjust it if necessary to conform to that standard. In air conditioners, the only parts that occasionally need calibrating are thermostats. Most mechanical thermostats use a bimetal to measure the temperature with a mercury bulb mounted on it to do the switching. These are position sensitive. The tilt of the bimetal controls the calibration of the thermostat.

To check the calibration you should follow these steps:

1. Place an accurate thermometer next to the thermostat and wait for its reading to stabilize.
2. Move the thermostat to its lowest setting.
3. Slowly raise the thermostat setting and note the temperature where the mercury rolls from one end of the bulb to the other.
4. Slowly lower the thermostat setting and note the temperature where the mercury rolls back to the other end of the bulb.
5. The bulb should turn off and on at either side of the actual temperature.

For example, if the actual temperature is 75°, the bulb should switch just above and below 75°. The most common cause of thermostat calibration problems is installation. If a mercury bulb thermostat is not mounted level on the wall, it will be out of calibration. The fix is to level the thermostat. Some mercury bulb thermostats can be calibrated using a small wrench to adjust the tilt of the mercury bulb. However, you should check to see if the thermostat is level before adjusting it. A few electronic thermostats can be calibrated by turning a small trim pot. When calibrating either type of thermostat you should make sure the thermostat is at room temperature, that the thermometer you are using is accurate, and that you avoid breathing on and handling the thermostat. Your body heat will cause it to read a few degrees higher.

TECH TIP

Many instruments can be ordered with certified NIST calibration. These instruments have been sent to a laboratory where the instrument was calibrated according to NIST standards. Many jobs in testing and balancing or combustion efficiency testing require certified calibrated instruments.

90.18 SCHEDULING PARTS CHANGES

All systems have parts that wear out. Scheduling replacement of these parts near the end of their expected service life can save system shutdowns and emergency calls. The advantage to the customer is reliable operation. A gas furnace's hot surface igniter is an example of a part that might be considered for a replacement schedule.

90.19 SAFETY CHECKS

A system that is not safe should never be left in operation. Systems should be inspected for possible safety hazards before work begins and before leaving then job site. Potential hazards should be corrected before proceeding with any work. Before operating the equipment, ensure the following:

- All equipment is properly grounded (Figure 90-64).
- Wire size and type are appropriate for the application.
- All electrical wiring passes through strain relief when entering equipment.
- All equipment, ductwork, wiring, and piping are properly supported.
- All moving parts are covered or protected by a safety guard.
- Combustion appliances have adequate combustion air and venting.
- Volatile fluids and other combustibles are not stored near the equipment.

Operational safety checks include the following:

- Current draw and temperature of power wiring during operation
- Pressure in vent system of combustion appliances

Figure 90-64 All electrical equipment should be properly grounded.

- CO level in combustion gases for combustion appliances
- CO level in equipment room for combustion appliances

UNIT 90—SUMMARY

The aim of planned maintenance is to extend the life of the equipment and keep it running efficiently. Planned maintenance also reduces emergency maintenance. All maintenance calls should start with a visual inspection, paying particular attention to safety issues. A planned maintenance call typically consists of routine maintenance, a prestart inspection, an operational check, and troubleshooting if needed. Many important operational characteristics can be found on the equipment's data plate or inside the service panels. During a planned maintenance service call, the technician has an opportunity to make the job easier in the future.

WORK ORDERS

Service Ticket 9001

Customer Request: Spring Air-Conditioning Checkup

Equipment Type: R-22 Split-System Air Conditioner, Horizontal Blower Coil in Crawlspace

During the initial prestart visual check, the technician notices water around the indoor unit and a very dirty filter. The technician changes the air filter, checks the evaporator and sees no ice, and operates the system. The airflow is noticeably low and the suction line starts to frost. System readings are:

Outside ambient	80°F
Return air	78°F
Supply air	50°F
Suction pressure	55 psig
Liquid-line pressure	175 psig
Suction-line temperature	30°F
Liquid-line temperature	84°F

The low suction pressure and low superheat point to an airflow problem. The water is a result of a plugged drain, which is complicated by ice forming on the evaporator. The technician concludes that the evaporator coil and drain pan both need cleaning.

Service Ticket 9002

Customer Request: Electric Furnace Fall Check

Equipment Type: 15 kW Electric Furnace Installed in a Closet

A technician is sent to do a fall check on an electric furnace. The voltage to the unit with the unit off is 240 V, the nameplate voltage. The technician checks the voltage at the fuse block with the unit operating and finds 240 V. When checking the voltage to the electric strips, there

is 240 V on two strips, but only 210 V on the third strip. There is a 30 V drop across the sequencer contacts, and the sequencer temperature is noticeably higher than the rest of the control panel. The technician concludes that the sequencer contacts are defective and changes the sequencer.

Service Ticket 9003

Customer Request: Gas Furnace Fall Check

Equipment Type: 80 Percent Upflow Furnace in Basement

A technician is called to perform a fall preseason check on a gas furnace. This customer has the furnace serviced every year and there is no record of any problems. The customer finished the basement over the summer and the furnace that was in an open basement is now in a small closet. The technician performs the furnace check with the closet door open and finds no problems. However, the technician wonders if the furnace will perform as well with the closet door closed because there are no visible combustion air openings. The furnace is operated with the door closed, and 15 minutes after lighting, the flames start to turn yellow and lazy. The technician's CO monitor indicates high levels of CO in the closet. The technician shuts down the furnace and concludes that the closet needs to have combustion air openings added for safe operation of the furnace. The open basement provided enough combustion air, but the unventilated closet does not.

Service Ticket 9004

Customer Request: Heat Pump Fall Check

Equipment Type: Split-System Air-Source Heat Pump

A technician is called to perform a fall check on the heat pump. The outside temperature is 50°F. While operating the unit on first-stage heat, the technician notices that the temperature rise across the indoor coil is only 10°F. The airflow is measured and found to be within specification for that unit. Further checks indicate that the refrigerant pressures are lower than expected using the heating performance check chart. The technician concludes that the unit is undercharged. The technician looks for leaks and finds a small leak at a flare joint. Tightening the flare stops the leak. The refrigerant is recovered, the system evacuated, and a full charge of refrigerant is weighed in according to the manufacturer's specifications.

Service Ticket 9005

Customer Request: Spring Air-Conditioning Checkup

Equipment Type: Split-System Air Conditioner with an Upflow Furnace in a Mechanical Closet

A technician is called to perform a spring check on a split-system air conditioner. The technician has to move cardboard boxes of Christmas ornaments stacked between the gas furnace and gas water heater to get to the

air filter. After concluding the checkup, the technician moves the boxes out of the furnace room and informs the homeowner that storing flammable items next to the furnace and water heater is dangerous.

Service Ticket 9006

Customer Request: Spring Heat Pump Checkup

Equipment: Packaged Air-Source Heat Pump, Filter Grille in Hall

A technician is called to do a spring check on an air-source heat pump. The technician finds a new high-efficiency electrostatic filter from DIY Depot in the filter grille. The airflow is noticeably low and the indoor coil starts to freeze over. The technician checks the indoor coil and finds it clean. When the high-efficiency filter is replaced with a standard filter, the airflow improves and the coil does not freeze. The technician informs the homeowner that the filter she was using had too much pressure drop for the system to operate correctly and offers to have a company representative discuss ways of improving the filtration without choking off the airflow.

UNIT 90—REVIEW QUESTIONS

1. List the four phases of a planned maintenance service call.
2. What is the purpose of checking the supply voltage both before and after operating the system?
3. Name key safety aspects of combustion appliances that should be checked on a planned maintenance service call.
4. List operational checks to make during an air-conditioning planned maintenance service call.
5. Why should caution be exercised when replacing a low-efficiency air filter with a higher-efficiency air filter?
6. How can performing planned maintenance save the customer money?
7. How does planned maintenance improve system reliability?
8. How can the technician determine what the system voltage parameters are?
9. How can the heating operation of a heat pump be checked without gauges?
10. The supply voltage to a system drops below the minimum voltage when the unit is operated. What could be causing this?
11. What color should the flames be in a correctly adjusted gas burner?
12. List the items to be checked when servicing a belt-drive system.
13. How can a worn belt be identified?
14. How is a temperature-pressure-relief valve on a hot water boiler tested?
15. Describe how sound is used in predictive maintenance.
16. Discuss the difference between predictive maintenance and planned maintenance.
17. What side of an air-conditioning A coil generally needs cleaning?
18. How does the technician know which way to install an air filter?
19. List some maintenance items that can be inspected visually.
20. How are water pumps in hydronic heating systems checked?

UNIT 91

Refrigeration System Cleanup

OBJECTIVES

After completing this unit, you will be able to:

1. list the data that should be recorded for baseline measurements.
2. explain the need for system cleanup after a compressor burnout.
3. explain how to clean up a system after a compressor burnout.
4. describe methods of performing a compressor-oil acid test.
5. discuss the safety issues in debrazing refrigeration components.
6. describe the procedure for flushing a refrigeration system.

91.1 INTRODUCTION

Refrigeration system component failures are often accompanied by system contamination. Compressor failures are often accompanied by system contamination. The contamination can be caused by a compressor failure. Contamination can also be a contributing factor in causing the compressor failure. Either way, leaving the contamination is certain to shorten the life of any replacement compressor and reduce system efficiency. Servicing a refrigeration system after a major component failure should always include system cleanup. One of the best ways to determine that a cleanup was successful is to compare the final operating conditions to the baseline performance data that were collected when the system was first installed.

91.2 BASELINE PERFORMANCE DATA

Baseline performance data comprise a record of all the system performance specifications when the system is operating as designed. Baseline performance shows what the system actually does in that particular installation, so it provides a benchmark to real operating conditions that are specific to that unit and application. Baseline information should include operating conditions, system pressures and temperatures, system superheat and subcooling, air or water temperature difference across both the evaporator and condenser, and amp draw of all motors—especially the compressor. Figure 91-1 shows a list of readings that should be collected for baseline data measurements.

It is a very good idea to collect baseline performance data on all new systems to allow comparison later in the life of the unit. System baseline performance can provide a valuable set of data for comparison when servicing a system. The effectiveness of a system cleanup can be determined by comparing the system operating characteristics after the cleanup to the baseline data collected when the system

was first installed. System operating characteristics should be checked after any major repair and compared to the baseline data. System baseline data can also be measured just prior to any major change in the system. Baseline performance measurements are often taken when replacing an ozone-depleting refrigerant with a newer, non-ozone-depleting replacement. The baseline performance data allow the system operating characteristics with the new refrigerant to be compared to the refrigerant the system was designed to use.

TECH TIP

Compressor manufacturers and refrigerant suppliers both recommend taking baseline measurements prior to changing the refrigerant in a system to a newer replacement refrigerant. You should get the system operating as close to the manufacturer's specifications using the original refrigerant before proceeding with any refrigerant conversion.

91.3 CAUSES OF REFRIGERATION SYSTEM CONTAMINATION

System contamination is often the result of improper installation. Common installation-related contaminants include carbon, oxides, air, and water. Additional contaminants can form later as a result of these, including acids and hydrolyzed compressor lubricant. Oxides are formed during brazing without using an inert gas. Oxygen in the air combines with the heated metal parts to form metal oxides. These oxides can come loose and collect in bearings and in the metering device. Figure 91-2 shows a screen that is stopped up by copper oxide deposits as result of brazing without nitrogen.

TECH TIP

Newer systems using HFC refrigerants and polyol ester lubricants are less tolerant of oxides than older HCFC systems, which use mineral oil. HFC refrigerants and ester-based lubricants are strong solvents. They will scrub oxides off the walls of oxidized tubing and deposit them in metering devices, screens, and orifices.

Figure 91-2 Screen that is stopped up by copper oxide deposits.

Air and moisture are left in the system when the system is not properly evacuated. Noncondensables, such as air and nitrogen, take up space in the condenser and raise the system high-side pressure. This increases the compression ratio, decreases the system capacity, and increases the compressor operating temperature. The higher operating temperatures encourage acids to form by chemical reactions between the refrigerant, air, and water. The acids then attack the system components from the inside out. Moisture left in the system can freeze up at the metering device, restricting the flow of refrigerant and severely decreasing system capacity.

TECH TIP

Newer systems using HFC refrigerants and polyol ester lubricants are more adversely affected by moisture than older HCFC systems, which use mineral oil. Ester based lubricants are cousins to soap. Polyol ester is a hygroscopic lubricant—water is attracted to it. They break down when mixed with water in the presence of metals and heat to form soapy deposits that stop up metering devices, screens, and orifices throughout the system.

System contamination can also be the result of a major compressor burnout. Hermetic compressor motors are surrounded and cooled by the refrigerant that they are pumping (Figure 91-3). When the compressor motor burns out, carbon compounds contaminate the refrigerant and oil. Contaminants can be pumped throughout the system if the compressor motor burns out slowly. Figure 91-4 shows a burned-out hermetic compressor motor. If

Figure 91-3 Hermetic motor in shell.

Figure 91-4 Burned hermetic compressor motor.

the compressor has operated at elevated temperatures for a period of time, the compressor oil will be carbonized. If this carbon is left in the system, it can ground out the new compressor by providing a conductive path between the motor terminals and the shell because the electrical terminals are exposed inside the shell (Figure 91-5). Acids left in the system can attack system components, including the compressor windings.

91.4 EFFECTS OF SYSTEM CONTAMINATION

Problems caused by system contamination range from loss of operating efficiency and higher operating cost to failure of system components and shorter system life. All these problems cost the customer money, so it is in the customer's best financial interest to clean up contaminated systems. It will help technicians working on chronically poor-performing systems to recognize the effects of some common contaminants.

Figure 91-5 Compressor terminals grounded by carbon.

Carbon

Carbon particles circulating with the refrigerant and oil can plug small holes in refrigeration components, such as screens, metering devices, control capillary tubes, and suction-accumulator oil-return holes. Carbon can also cause internal shorts and grounds on hermetic compressors (see Figure 91-5). To clean up a system contaminated with carbon: recover the refrigerant, flush the system, install filter driers, evacuate the system, and charge the system with clean refrigerant.

Noncondensables

Noncondensables, such as air or nitrogen, take up space in the condenser and raise the system high-side pressure. This increases the compression ratio, which increases the compressor amp draw and decreases the compressor capacity. The end result is decreased system capacity, increased compressor operating temperature, and increased system operating costs. The only way to remove noncondensables once they are in the system is to recover the entire charge, evacuate the system, and recharge it with the correct refrigerant charge, being careful not to reintroduce noncondensables during the charging process.

Moisture

Moisture is normally introduced when air is let into the system, because nearly all air contains moisture. Moisture attacks the metals inside the system, causing corrosion and oxidation. A drop of water can freeze up at the metering device, causing a restriction. The drop in system capacity can be dramatic. A restriction caused by moisture will often clear if the system is turned off and allowed to warm up. When the system is restarted, the problem appears to have gone away. But the problems reappear when the moisture makes its way back to the metering device. To remove moisture from a system, recover the refrigerant, install a filter drier, evacuate the system down to 500 microns, and recharge with clean refrigerant.

Acid

Acid is rarely introduced into the system; instead, it is formed by the cumulative effect of other contaminants. The combination of air, water, and refrigerant at elevated temperatures can react chemically to form acids that are concentrated in the compressor oil. Most of the materials inside the system can be attacked by acid, literally eating the system away from the inside out. Another effect of acid is copper plating. Acidic oil dissolves copper from the inside of the lines and deposits it in other places, like compressor valves and bearing surfaces. A system with a coppery sheen on internal steel parts has been operating under acidic conditions (Figure 91-6).

91.5 OIL ACID TEST

The compressor oil is a good indicator of the overall system cleanliness because oil acts like a scavenger, collecting contaminants from all over the system. After installing

Figure 91-6 Copper plating inside compressor.

TECH TIP

New high-efficiency systems only perform at their rated capacity and efficiency if they are properly matched with a listed AHRI coil and installed according to the manufacturer's specifications. System contamination can adversely affect the system performance and shorten the equipment life. A customer that has purchased an expensive new high-efficiency system will not be pleased when it performs no better than the older unit being replaced.

a replacement compressor, the compressor oil should be regularly monitored to ensure that the system stays clean. Ideally, the compressor oil should be checked during the first week of operation after the cleanup. Acid is the primary contaminant to look for. Oil can appear clean but still have a high acid content. Two types of oil acid tests are available: kits that use a physical oil sample and indicators that allow a small amount of refrigerant to pass through them without getting an oil sample (Figure 91-7). In both cases, an indicator chemical changes color when acid is present.

The liquid oil acid test kits can only be used with compressors that have an oil drain plug, such as open compressors and semihermetic compressors. Remember that the compressor crankcase is under pressure. You must valve off the compressor and recover the refrigerant in the crankcase before taking the oil sample. Leave a slight pressure in the crankcase of 1 to 2 psig to help push the oil out without letting air in. A specific quantity of oil is collected and mixed with the indicator chemical. Acid is indicated by a change in color (Figure 91-8). Follow the manufacturer's instructions for specific details.

Figure 91-7 Oil acid test strip and test kit.

Figure 91-8 Color change indicating acid.

It is not practical to get an oil sample with hermetic compressors because they must be physically removed to change the oil or take an oil sample. Indicators are available that get a trace amount of oil by purging a small amount of refrigerant through them while the system is operating, making it unnecessary to collecting an oil sample. These indicators typically connect to the suction line with the system operating, reducing the refrigerant pressure on them. Refrigerant vapor is purged through them for a few seconds. The indicator changes color if there is acid in the refrigerant vapor flowing through the indicator tube (Figure 91-9).

If the test indicates that the compressor oil is acidic, the compressor oil and system filter driers should be changed. In the case of a hermetic compressor, the oil is normally not changed due to the impracticality of removing the compressor to change the oil. It is possible to clean up a system through repeated filter drier changes; it just takes longer.

Figure 91-9 Strip color change showing acid.

91.6 STAGES OF REFRIGERATION SYSTEM CLEANUP

The stages in cleaning up a system are as follows:

1. Recovering the contaminated refrigerant
2. Changing the contaminated compressor oil
3. Flushing the lines and coils
4. Performing any system modifications or repairs
5. Installing liquid-line and suction-line driers
6. Evacuating and charging the system
7. Operating the system and checking performance data

91.7 RECOVERING CONTAMINATED REFRIGERANT

Contaminated refrigerant should be recovered into an empty recovery cylinder marked "Contaminated" to keep it from contaminating other relatively clean recovered refrigerant (Figure 91-10). Charges for destroying contaminated refrigerant can become expensive.

SAFETY TIP

If you are recovering R-410a, make sure all your equipment is rated for R-410a, including the gauges, hoses, recovery machine, filter, and recovery cylinder. Using equipment that is not specifically designed for R-410A can be dangerous. Equipment not rated for R-410A can rupture due to its higher pressures.

The refrigerant should pass through a filter before entering the recovery unit to reduce the amount of contaminants entering the unit, thereby prolong its life (Figure 91-11). The refrigerant should not be reused. Contaminants that remain in the refrigerant will shorten the life of any new components and reduce system efficiency. The cost of new refrigerant is minor compared to the cost of a new system. Instead, the contaminated refrigerant should be returned to

Figure 91-10 Recovery cylinder marked "Contaminated."

Figure 91-11 Filter inline to recovery unit.

a refrigerant processor, who can either reclaim or destroy it. The refrigerant processor may charge for disposing of the contaminated refrigerant depending upon the level of contamination and the capabilities of the refrigerant processor. Keeping severely contaminated refrigerant separated from other recovered refrigerant reduces your refrigerant processing costs.

Ideally, your gauges should be connected to both the suction line and the liquid line. Figure 91-12 shows recovery connections using a standard two-valve manifold. Recovering liquid first speeds the recovery process and

Figure 91-12 Recovery unit connections to manifold and unit.

maximizes contaminant removal. For liquid recovery, only the high-side manifold hand wheel will be opened and the recovery unit valve(s) will be set for liquid (Figure 91-13). Some gauges have a sight glass that can be used to monitor the refrigerant, allowing you to see when liquid is no longer being recovered (Figure 91-14). The temperature of the middle gauge port is also an indicator. Liquid refrigerant flashes as it passes through the gauges, causing the port to become cold. When only vapor refrigerant is flowing through the gauges, the port warms back up.

Figure 91-13 Recovery unit valve set to liquid recovery.

Figure 91-14 Sight glass in gauges.

After removing as much liquid as possible, switch to vapor recovery. Vapor should be recovered from both sides of the system to avoid pressure drop through the compressor and metering device. During vapor recovery, both manifold hand wheels will be opened and the recovery unit valve(s) will be set for vapor (Figure 91-15). You should recover vapor down to the recovery level specified by the EPA. Recovery may be stopped before reaching the specified level on systems with leaks, but in no case should the final system pressure be above 0 psig.

Figure 91-15 Recovery unit set for vapor recovery.

91.8 REFRIGERANT COMPONENT REMOVAL

Refrigeration system service often involves the removal of components such as the compressor, metering device, or filter driers. The first step is always to make sure there is no pressure on the component being removed. Some components will require recovery of the entire refrigerant charge: a hermetic compressor is a good example (Figure 91-16). Some components can be isolated, minimizing the amount of refrigerant recovery. A semihermetic compressor with manual service valves can be isolated from the rest of the system by front-seating both service valves (Figure 91-17). Systems with king valves or liquid-line service valves can often be pumped down before removing metering devices or filter driers (Figure 91-18).

Mechanical Connections

Components that have mechanical connections are generally easier to remove and replace. You should always use two wrenches: one for a backup wrench to hold the part

Figure 91-16 Hermetic compressor in system.

Figure 91-17 Semihermetic compressor with service valves.

Figure 91-18 King valve for pumping down.

that should not turn and the other to do the turning. Always use correct fitting, properly sized wrenches (Figure 91-19). Fixed wrenches are preferable to adjustable wrenches. Pliers, vise grips, Robogrips, and channel locks should not even be considered (Figure 91-20). As a precaution, loosen

Figure 91-19 Two wrenches removing part.

Figure 91-20 Channel locks should not be used on flare nuts or valves.

the connection and listen for escaping refrigerant before completely removing the connection. Most mechanical connections will turn easily by hand after the initial loosening. A connection that remains tight after the first partial turn may still have pressure behind it. Do not stand directly in line with the connection being removed in case it is still pressurized. You do not want to be in the path in a worst-case scenario with a large accidental release of refrigerant. Ideally, you should have the replacement part ready to go so that it can be installed immediately after removing the old component. If this is not possible, the opening should be capped or plugged to prevent system contamination from air and moisture (Figure 91-21).

Figure 91-21 Line is capped to prevent contamination.

Brazed Connections

There are two general methods for removing components that are brazed in: debrazing and cutting. Debrazing has the advantage of leaving the copper tubing in the original configuration. This makes exact replacement components easier to fit and reduces the number of brazed connections necessary. Debrazing has the disadvantage of being inherently more dangerous. Debrazing can also create more system contamination. Filter driers should not be debrazed because heating them can drive contaminants captured in the driers back into the system.

It is crucial to ensure that the component is not pressurized before debrazing. Although most of the refrigerants we work with are nonflammable, the refrigerant oil is flammable. A sudden release of refrigerant and oil can ignite with a flamethrower effect, even with an A1 refrigerant. When debrazing a compressor, cut open the process tube before proceeding to relieve any pressure left in the compressor (Figure 91-22). Even with the refrigerant recovered, a short puff of flames often comes out of the connection when it is pulled loose (Figure 91-23). Another hazard is created by the

Figure 91-22 Cut process tube on hermetic compressor.

Figure 91-23 Flames coming from de-brazed connection.

Figure 91-24 Tubing broken off from bad de-brazing.

decomposition of halogenated refrigerants. Even after recovery, there is still enough refrigerant left inside the system to cause a problem during debrazing. The refrigerant breaks down to form poisonous gases in the presence of flames. It can be very difficult to breathe if you are positioned over the opening. Debrazing is more difficult than brazing. The entire joint must be molten before you can pull the tubing out. Tubing can break off in the joint if you try to pull it out before all the braze material is molten (Figure 91-24). For safety reasons, some manufacturers recommend cutting compressors out instead of debrazing them.

91.9 CHANGING CONTAMINATED COMPRESSOR OIL

The refrigerant oil acts like a scavenger, absorbing contaminants as it circulates through the system. The compressor can hold large quantities of contaminants suspended in the oil and settled at the bottom of the crankcase. If the compressor is being changed, this contaminated oil will be removed with the compressor. However, if the compressor is not being replaced, the compressor oil should be changed whenever practical. The fastest way to clean a contaminated system is to keep changing the oil until it is clean. The oil can often be changed in semihermetic and open compressors, but it is not practical to change the oil in a hermetic compressor.

SAFETY TIP

Contaminated compressor oil can sometimes be very acidic. It should always be handled as if it is acidic. Severe burns can occur from contacting acidic contaminated compressor oil.

Most open compressors and semihermetic compressors have an oil drain plug (Figure 91-25). Remember that the compressor crankcase is under pressure. You must valve off the compressor by front seating the suction and discharge service valves, and recover the refrigerant in the

Figure 91-25 Oil drain plug on compressor.

Figure 91-26 Oil fill plug.

crankcase before removing the drain plug. Drain the oil into a clean, empty container so that the level of contamination can be checked. Measure the amount of oil removed, and replace just that much oil. There will be more oil out in the system. If you fill the crankcase, you will most likely have too much oil in the system. Remove the fill plug and pour in the new oil (Figure 91-26). Because the compressor was opened to the atmosphere, it must be evacuated. However, only the compressor needs to be evacuated, because it was isolated from the rest of the system when you front-seated the service valves. This should not take long. After the compressor is evacuated, you can backseat the compressor service valves and put the system back into operation. If the compressor has a sight glass, observe the oil level after starting the compressor to make certain it is correct.

91.10 SYSTEM FLUSHING SOLVENTS

The lines and coils will be coated with refrigerant oil. If the system is contaminated, the oil in the lines and coils may also be contaminated. A nitrogen purge can blow out some of these contaminants, but many contaminants will remain in the system. The lines and coils can be flushed with a solvent that is manufactured specifically for cleaning refrigeration systems to remove the residual contaminants. Do not use general-purpose solvents, especially not flammable petroleum products.

Figure 91-27 Oil-return hole in accumulator.

SAFETY TIP

An inert gas such as nitrogen or CO₂ may be used to purge the system of contaminants and residual solvent. NEVER use oxygen or compressed air because it can create an explosive mixture with the refrigerant oil in the system.

You should never flush through refrigeration components that act as natural traps, such as liquid receivers, accumulators, or compressors. Contaminants will flush in but not out. If a receiver or accumulator is suspected of holding a large amount of contaminants, it should be replaced. Accumulators in particular have a small oil-return hole. If this becomes stopped up, oil will be trapped in the accumulator when the system operates and the compressor is sure to fail eventually from lack of lubrication (Figure 91-27). Filter driers should be replaced, not cleaned. Do not flush through the metering device; the restriction in the metering device can trap small particles and stop it up. Expansion valves and orifices should be removed prior to flushing the evaporator coil.

TECH TIP

Most system flush products are low-pressure chemicals that remain a liquid while flushing but will easily evaporate from the system. You do not want to use a product that will remain in the system. Ideally, any flush product that remains in the system will evaporate when you pull a vacuum on the system before recharging it.

91.11 FLUSH PROCEDURE

Make certain the system refrigerant has been recovered before proceeding. You cannot flush systems that still have a refrigerant charge. Components that cannot be flushed should either be removed or bypassed. You should only be

Figure 91-28 Front-seated split-system shutoff valves.

flushing lines and coils—not compressors, accumulators, receivers, metering devices, or filter driers.

With split systems that have installation valves, front-seating the valve will isolate the line from the unit (Figure 91-28). This will direct the flushing agent through the valve and into the lines, not into the system. The end of the lines at the blower coil should be disconnected or cut and placed in a container to catch the contaminated oil and debris. The lines should first be purged with nitrogen to blow out as much oil and debris as possible. Nitrogen is much cheaper than flushing solvent. Adjust the nitrogen regulator to between 100 and 120 psig and purge with nitrogen for 5 minutes. Never exceed the system's low-side design pressure.

SERVICE TIP

For best results, remove the cores from Schrader valves before purging and flushing through the valve and use a connecting hose with no core depressor. The pressure drop across a Schrader valve is dramatic. Removing the core and core depressor increases the flow of the purging gas and flushing solutions, improving the effectiveness of the purge and flush operation.

After purging with nitrogen, close the nitrogen cylinder, back out the regulator, and disconnect the nitrogen hose from the system. You are now ready to flush the lines with flushing solvent. The specific procedure may vary depending upon the solvent manufacturer. Always read and follow the solvent manufacturer's recommendations.

SAFETY TIP

Always use a regulator and pressure-relief valve when using nitrogen cylinders. Never attempt to connect the nitrogen cylinder directly to the system without going through a regulator.

Typically, the solvent comes in a disposable metal cylinder containing both the solvent and propellant. The cylinder must be inverted to deliver the solvent (Figure 91-29). Flushing time varies depending upon the type of solvent, the size of the line, and the length of the line being flushed. This can be from 30 seconds to several minutes. Ideally, you

Figure 91-29 Inverted flushing solvent cylinder.

want to flush until no oil or debris comes out of the line. Often you may not be able to see the other end of the line. In these cases, use multiple flushes of 1 to 2 minutes and examine the contents of the container between flushes. Finally, reconnect the nitrogen and purge at 100 to 120 psig until no solvent comes out.

SAFETY TIP

Many flushing solvents come in disposable cylinders. These cylinders should never be exposed to system pressure or pressure from a nitrogen cylinder because they could explode under these higher pressures. To avoid any chance of accidentally pressurizing the disposable cylinder, the cylinder of flushing solvent should never be connected to the system at the same time as a nitrogen or refrigerant cylinder.

91.12 USING FILTER DRIERS FOR SYSTEM CLEANUP

Some of the particles loosened by the flushing procedure are not removed from the system. Filter driers should be added to remove the remaining contaminants and protect the refrigeration system components. A liquid-line filter should be added to the liquid line to protect the metering device; a suction-line filter should be added to protect the compressor (Figure 91-30). Specially designed cleanup filter driers should be used following a flushing procedure. Cleanup filter driers are designed to maximize acid and particle removal; they can remove particles down to 3 microns in size (Figure 91-31).

Drier sizing should take into account both the volume of refrigerant in the system and the pressure drop across the drier. In general, driers should be sized for a pressure drop of 1 psig or less. Filter drier manufacturers provide sizing guidelines on the box and in the instructions that come with the drier (Figure 91-32). Suction filters are sized for a

Figure 91-30 Liquid-line and suction-line filters.

Figure 91-31 Special cleanup filter.

pressure drop equivalent to a 2°F saturation temperature drop. A pressure drop equivalent to a 5°F saturation temperature drop is acceptable for temporary application.

Although regular filter driers can also remove acid and particles, their primary purpose is moisture removal. The two desiccants used most often in filter driers are molecular sieve and activated alumina. Molecular sieve is superior at moisture removal but is not very effective on inorganic acids. Activated alumina is effective on both organic and inorganic acids but is less effective at moisture removal. Activated charcoal is often added to cleanup driers to remove hydrocarbon residues and wax. Driers that are designed primarily for moisture removal will contain high

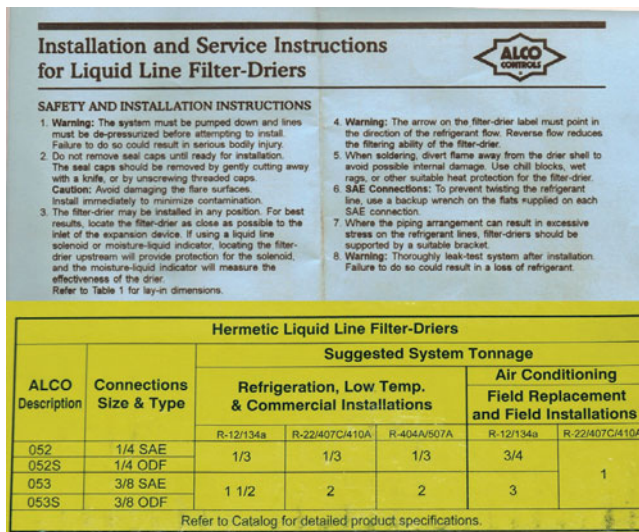

Figure 91-32 Filter drier application notes on box and sheet.

levels of molecular sieve but may have little or no activated alumina for acid removal. Cleanup driers contain high levels of activated alumina and activated charcoal to handle acids and hydrocarbon residues. Typically, cleanup driers also offer high levels of filtration for particles down to 3 microns compared to 30 microns for standard driers.

Another difference is that regular driers are designed to remain in the system. Cleanup driers are removed after they have performed their job. Logically, driers should be removed after collecting contaminants simply to remove the contaminants from the system. Suction-line filters in particular are designed to be removed from the system after the system is clean. This not only removes the contaminants from the system but also minimizes pressure drop in the suction line.

TECH TIP

Some manufacturers will void the compressor warranty if a suction-line filter drier is left on the system indefinitely.

There is a slight refrigerant pressure drop across any filter drier, even a clean one. The refrigerant pressure drop increases when the drier has absorbed all the contaminants it can hold. Most filter driers should be replaced whenever the pressure drop across the drier exceeds 2 psig, because this pressure drop causes a loss in system efficiency. Pressure drop across a liquid-line filter can cause flash gas in liquid lines, reducing overall system capacity by reducing the amount of liquid delivered to the metering device. Suction-line filter pressure drop reduces the suction pressure to the compressor, increasing compression ratio. Many filters come with Schrader valves to make checking the pressure drop across the filter easy (Figure 91-33). Another way to check for a restricted filter drier is to measure the temperature on either side of the filter drier with the system operating. A measureable difference between the inlet and the outlet indicates a restriction (Figure 91-34).

Figure 91-33 Gauge ports on filter drier.

Figure 91-34 Temperature drop across filter.

91.13 EVACUATE AND CHARGE

The system should be reassembled, leak tested, evacuated, and charged according to the manufacturer's specifications. Failure to properly evacuate the system will introduce new contaminants. There is no point spending time and money cleaning up a system and then undoing all your work by not properly evacuating and charging the system. A leak test with nitrogen should be the first step after reassembly. Finding and repairing any leaks will save time in the long run. Refer to Unit 29 for more detail on refrigerant leak testing.

Next, release the nitrogen and evacuate the system to under 500 microns. It is especially important to get a good evacuation on a system after a cleanup. Refer to Unit 30 for more detail on system evacuation.

Finally, weigh in the manufacturer's specified charge. You may need to add additional charge for the refrigerant capacity of filters, which is typically stated in the instructions (Figure 91-35). If the refrigerant is being changed to a more environmentally friendly refrigerant, remember that the weight of the correct amount of the new refrigerant will be different from the older refrigerant. Older CFC and HCFC refrigerants are denser than most replacement HFC refrigerants. It does not take as much weight of the newer refrigerants to fill up the same space, so less refrigerant is required. Refer to the equipment manufacturer and the refrigerant producer for technical specifications and conversion directions. For more detailed discussion of refrigerant charging, refer to Unit 29.

Weight of Refrigerant in Ounces - EK Series						
Unit Size	R12		R22		R502	
	Liquid temp.		Liquid temp.		Liquid temp.	
	75°F	125°F	75°F	125°F	75°F	125°F
03	2.9	2.6	2.6	2.3	2.7	2.4
05	6.5	5.9	5.9	5.3	6.1	5.4
08	8.3	7.6	7.5	6.8	7.8	7.0
16	10.2	9.4	9.3	8.4	9.7	8.6
30	28.7	26.1	26.1	23.5	27.1	24.0
41	40.0	36.4	36.4	32.5	37.8	33.4
75	72.4	65.8	65.8	59.2	68.4	60.5

Figure 91-35 Refrigerant capacity of drier on instruction sheet.

91.14 OPERATE AND ADJUST

System performance should be verified by measuring and recording key system operating performance specifications. These should then be compared to the manufacturer's specifications and any available system baseline performance data. The same measurements used for baseline performance should be checked, including the following.

Compressor Data

- Suction pressure
- Suction temperature
- Discharge pressure
- Discharge temperature
- Amp draw

Condenser Data

- Temperature of air or water in
- Temperature of air or water out
- Condenser flow in CFM for air or GPM for water
- Liquid-line temperature

Evaporator Data (Including Metering Device)

- Entering-air wet-bulb temperature (for air coils)
- Temperature of air or water in
- Temperature of air or water out
- Evaporator flow in CFM for air or GPM for water
- Liquid-line temperature
- Suction-line temperature

UNIT 91—SUMMARY

System contamination can cause restricted metering devices and compressor failures. Contamination can be caused by improper installation and service or a catastrophic compressor failure. Typical system contaminants include moisture, noncondensables, carbon, acid, and metal shavings. Systems should be cleaned before installing a new compressor to prevent the contaminants from killing the new compressor. Cleaning methods include nitrogen purging, flushing with solvents, filter installation, changing the compressor oil, and system evacuation. Technicians should

only purge lines and coils. Do not purge through components such as the compressor or accumulator, because they can trap contaminants. Contaminated compressor oil can be identified by performing an oil acid test. Two types of oil acid tests are available: kits that use a physical oil sample and indicators that allow a small amount of refrigerant to pass through them without getting an oil sample. The stages of system cleanup are recovering the contaminated refrigerant, changing the contaminated compressor oil, flushing the lines and coils, performing any system modifications or repairs, installing liquid-line and suction-line driers, evacuating and charging the system, operating the system, and checking performance data. Baseline performance data should be collected on all new installations. These data can be used for comparison later after major service or cleanup operations.

UNIT 91—REVIEW QUESTIONS

1. What are the most common types of refrigeration system contaminants introduced because of improper installation?
2. How does carbon affect a system?
3. What effect does the presence of noncondensables have on a system?
4. What system condition is indicated by copper plating?
5. What are the most common sources of refrigeration system contamination?
6. Explain how contaminants from a previous compressor failure can cause a replacement compressor to fail.
7. What is the purpose of collecting system baseline performance data?
8. List the system characteristics that are checked when taking system baseline performance.
9. List the stages of system cleanup.
10. Why does changing the compressor oil help clean up a contaminated system?
11. What is the difference between a regular filter drier and a cleanup filter drier?
12. Why should a cleanup filter drier always be used after performing a system flush?
13. Which refrigeration system components should not be flushed?
14. List the steps in flushing a system.
15. What are the two general types of oil acid tests available?
16. Why is it safer to cut out refrigeration components for removal rather than debraise them?
17. Why are suction-line accumulators particularly vulnerable to system contamination?
18. When retrofitting a CFC or HCFC system with a newer HFC refrigerant, why is the HFC refrigerant charge usually less than the original factory charge?
19. Why is a good evacuation critical after performing a system cleanup?
20. Describe the correct way to loosen a mechanical fitting when removing a refrigeration component.
21. Why should refrigerant from a compressor burnout be recovered into a separate cylinder marked "Contaminated"?
22. What factors are taken into consideration when sizing filter driers?
23. Why should suction-line filter driers be removed after the system is clean?

UNIT 92

Troubleshooting

OBJECTIVES

Upon completion of this unit, you will be able to:

1. discuss common questions customers ask service technicians.
2. outline the basic phases of troubleshooting.
3. outline an electrical troubleshooting procedure that uses the process of elimination.
4. discuss the use of common refrigeration system performance indicators in troubleshooting refrigeration problems.
5. explain how to use manufacturer-provided troubleshooting aids.

92.1 INTRODUCTION

Service technicians earn their living with their troubleshooting skills. Troubleshooting is the process of identifying problems, determining their cause, and correcting the cause of the problem. Effective troubleshooting requires problem solving, and the technician needs to do more than try to match symptoms with causes because most symptoms have many possible causes. Rather, technicians must understand exactly how equipment operates so they can analyze the cause of improper operation. Troubleshooting often requires performing tests on equipment, but taking a lot of readings is not troubleshooting. The data are worthless if they are not understood. Each test should take the technician a step closer to solving the problem. Most important, troubleshooting is not replacing parts until the system operates. Not only is this approach expensive, but it frequently fails to repair the problem. It is possible to replace all the parts and still have the original problem if the cause is not a defective component. A methodical approach to troubleshooting that is based on knowledge of fundamental system operation will result in less time spent overall, less cost in unnecessary replacement parts, and fewer mistakes. Technicians who practice systematic troubleshooting techniques can often correct problems in equipment that they have never seen before.

92.2 SIX CRUCIAL QUESTIONS ALL SERVICE TECHNICIANS MUST BE ABLE TO ANSWER

An important part of providing service is answering the customer's questions. Being prepared to answer questions completely and confidently builds the customer's confidence in the service technician. At the conclusion of a troubleshooting call, technicians should be able to answer six general questions:

- How is the equipment supposed to operate?
- What is the equipment doing wrong?
- What is the root cause of the problem?

- What specific tests or procedures were performed to determine the cause of the problem?
- How can this be corrected?
- How much will this cost?

How Is the Equipment Supposed to Operate?

Being able to explain how the equipment is supposed to operate makes explaining what is wrong easier. If the customer perceives that the technician does not understand the equipment, he or she will not have much faith in the technician's proposed solution.

What Is the Equipment Doing Wrong?

The technician should be able to identify what the equipment is doing wrong. What is the equipment doing that it should not do, or what is it not doing that it should do? Technicians should be able to clearly explain to their supervisors and to their customers what is incorrect about the operation of the equipment.

What Is the Cause of the Problem?

Of course, the customer wants to know exactly what is causing the problem. If possible, explain why this component or situation is causing the problem. The customer will have more confidence in a cause that can be logically explained. This is where being able to explain the system operation comes in handy.

What Tests Were Performed to Determine the Cause of the Problem?

Technicians should be able to explain to their supervisor or the customer what specific tests they did. Condemning parts or systems without testing is guessing. Technicians should keep an accurate log of all work performed. Repairing a system by replacing parts is expensive and may not solve the problem! Systems can malfunction for reasons other than bad parts. An air-conditioning system with

a dirty condenser may shut down because of high pressure. This does not mean that the high-pressure switch needs to be replaced or that the system is overcharged. In fact, replacing the high-pressure switch would have no effect on system operation.

How Can This Be Corrected?

Most customers will not be satisfied with simply finding out why their unit does not work; they want the problem solved. The service technician should be prepared to offer solutions. Remember that replacing a failed component is not necessarily the solution. Replacing a compressor that has experienced liquid slugging without addressing the cause of the slugging has not solved the customer's problem. The cause of the liquid slugging must also be found and corrected.

How Much Will This Cost?

A practical reason for recording all tests performed is that this information is generally used to generate bills. Many companies now use service pricing books to calculate the cost of a service call. Most price books are based on the specific services performed. It is very difficult to produce an accurate bill without a specific list of services performed.

The cost is the foremost question in the customer's mind. The service technician needs to be able to address this question, which is certain to be asked. Many companies now require their technicians to generate and present the bill. Even technicians working for companies that do not generate bills in the field should be prepared to explain the company's pricing policy.

SERVICE TIP

One way of avoiding conflict is to make sure the customer understands the company's pricing policies up front. Also, allow the customer to accept your proposed solution before implementing it. You should clearly explain the problem, the cause of the problem, and your proposed solution to the customer. Let the customer agree with the solution before implementing it.

92.3 SYSTEMS APPROACH TO TROUBLESHOOTING

The major processes involved in operating air-conditioning systems include the electrical, refrigeration, airflow, and combustion processes. To make the material manageable, the different processes are often discussed separately. However, technicians are called to work on the entire system, not an isolated part of it. All system components depend upon each other. In truth, it is difficult to examine any single aspect of system performance while ignoring the rest of the system.

Service technicians must understand the interrelationship between different system components and be aware of the effect one process has on the rest of the system. For example, low evaporator airflow in an air conditioner will

cause low suction pressures, causing the compressor to trip out on the low-pressure switch. What may initially look like an electrical problem, or a refrigeration problem, may in fact be an airflow problem. Similarly, refrigeration system problems can have an electrical cause. An inoperative evaporator fan motor can reduce the low-side pressure, but the solution is certainly not more refrigerant.

SERVICE TIP

The low-side pressure is closely tied to airflow or water flow over the evaporator. Reduced airflow over the evaporator reduces the amount of heat available for evaporating the liquid refrigerant. The refrigerant temperature starts dropping due to reduced heat load, and so the pressure also starts to drop. Airflow or water flow is the first possible cause that should be investigated when examining a system experiencing a low evaporator pressure.

Low evaporator airflow can also cause many other problems that are not as immediately obvious as low suction pressure. The low evaporator pressure that results from poor evaporator airflow can cause high compression ratio and loss of capacity. Low suction-gas superheat that results from poor evaporator airflow can damage the compressor by allowing liquid in the return-gas line.

SERVICE TIP

The high-side pressure is closely tied to airflow or water flow over the condenser. Reduced airflow over the condenser reduces the rate of heat rejection from the condenser. This causes increased refrigerant temperature and pressure. Airflow or water flow is the first possible cause that should be investigated when examining a system experiencing high condenser pressure.

Low condenser airflow can also cause other problems that are not as immediately obvious as high discharge pressure. The high discharge pressure that results from poor condenser airflow can cause high compression ratio and loss of capacity. High discharge pressure and reduced refrigerant flow can lead to compressor overheating because many compressors are cooled by the refrigerant they pump.

92.4 STAGES OF TROUBLESHOOTING

Troubleshooting can be broken down into several distinct steps, each step logically following the other:

- Understanding system operational sequence
- Preliminary system inspection
- Collecting operational data
- Recognizing what is operating incorrectly
- Testing to isolate the cause
- Recommending corrective action

92.5 UNDERSTANDING THE SYSTEM OPERATIONAL SEQUENCE

It is necessary to understand how a machine is supposed to operate to recognize when it is operating incorrectly. In most cases, this step should be accomplished before arriving at the job. It is possible to troubleshoot an unfamiliar system, but the first step is to understand how it operates. Sources of information on the system sequence of operation include the manufacturer's installation and operation and manuals, unit wiring diagrams, unit charging charts, and general textbooks. Some manufacturers provide detailed information about the unit operation on equipment panels. Increasingly, equipment and component manufacturers are providing specific information about current products on their Web sites. The Web site is often the best place to find the latest service bulletins and updates. The key point is that you must learn what the system is supposed to do and how it is supposed to do it before you can effectively troubleshoot it.

92.6 TYPICAL OPERATING SEQUENCES

Technicians should have an understanding of the basic sequence of operation for the most common types of systems they work on. Although all induced-draft furnaces do not use the same parts or work in exactly the same manner,

there are some basic operations that are common to most of them. The same can be said of air conditioners and heat pumps. Figures 92-1 through 92-5 show typical operating sequences for common residential systems.

The charts are read from the top down. Events that take place first are at the top; events that take place last are at the bottom. The items in a column occur in sequence, meaning that all the actions listed above an entry must occur before that action can take place. The events are in bold; details of each event follow.

92.7 PRELIMINARY SYSTEM INSPECTION

Do the easy things first! Many systems have simple problems like loss of power, loss of control voltage, dirty air filters, or dirty coils. It is never wrong to check the air filter or check to see how dirty a condenser coil is. There are several items that should be routinely checked on any service call:

- Is the thermostat or system control set correctly?
- Is the air filter clean?
- Is there enough airflow or water flow (depending on the type of unit)?
- Is the system operating voltage within the nameplate rating?
- Is the system control voltage correct?

AIR CONDITIONER OPERATING SEQUENCE			
Thermostat terminal R , Control Power, R must receive 24 volts for unit to work. The thermostat connects the control voltage at R to Y and G to control unit operation.			
Thermostat terminal Y , Cooling Y is energized anytime there is a call for cooling.		Thermostat terminal G , Indoor Fan In AUTO position, G is energized on a call for cooling. In ON position, G is energized all the time.	
Evaporator drain float switch Breaks Y signal if evaporator drain is full.		Indoor fan relay Closes contacts when coil is energized.	
Low-pressure switch Breaks Y signal if suction pressure is low.		Run capacitor Required for fan operation.	
High-pressure switch Breaks Y signal if discharge pressure is high.		Indoor fan motor	
Anti-short-cycle timer Prevents immediate restarting.

WATER-SOURCE HEAT PUMP SEQUENCE OF OPERATION			
R control power thermostat receives 24 volts at R terminal and sends it to the other terminals to control unit operation.			
Y compressor Y is energized in both first-stage heating and cooling.	G Indoor Fan AUTO energized on call for cooling. ON position energized all the time.	O Reversing Valve * B Reversing Valve O is energized in cooling to energize the reversing valve on most heat pumps. B is energized in heating to energize the reversing valve on a few heat pumps.	W2 Second-Stage Heat W2 is energized to energize the second stage heat. Not all water-source heat pumps have second stage heat.
Evaporator float switch Breaks Y signal if evaporator drain pan is full.	Indoor Fan Relay Closes contacts when coil is energized.	Reversing Valve Swaps functions of the indoor and outdoor coils. Energized in cool for most heat pumps. Energized in heat on a few heat pumps.	Heat Sequencer Close their contacts after a time delay when the coil is energized.
Liquid low-pressure switch Breaks Y signal if liquid pressure is low.	Run Capacitor Required for fan operation.		Thermal Overload The thermal overloads are really safety devices in series with the heat strips.
High pressure switch Breaks Y signal if discharge pressure is high.	Indoor fan motor Circulates air inside.		Strip heaters Come on for supplemental heat.
Anti-short-cycle timer Prevents immediate restarting.			
Compressor contactor Closed contacts when coil is energized.			
Run capacitor Frequently the fan and compressor run capacitors are both in one dual capacitor. Required for compressor operation.			
Start capacitor Required by some compressors to start.			
Potential relay Required if compressor has a start capacitor.			
Compressor			

Figure 92-3 Water-source heat pump sequence of operation.

INDUCED-DRAFT GAS FURNACE OPERATING SEQUENCE	
Manual reset rollout switches These shut down the system if the flames come outside of the normal combustion area. They may be after the R terminal on some furnaces.	
Thermostat terminal R , Control Power, R must receive 24 volts for unit to work. R connects 24 volts to W to start a call for heat.	
Thermostat terminal W , Heating W is energized when there is a call for heating.	Thermostat terminal G , Indoor Fan In AUTO position, G is NOT energized for heating. In ON position, G is energized all the time.
Manual reset auxiliary limit Auxiliary limits prevent the fan compartment from overheating. They are not typically found on upflow only furnaces.	Indoor fan relay Closes contacts when coil is energized.
Auto reset primary limit The primary limit shuts down the flames if the heat exchanger area overheats.	Run capacitor Required for fan operation
Induced-draft fan motor relay This is usually part of the furnace control board it energizes to operate the induced draft fan motor.	Indoor fan motor
Indoor-draft fan motor Creates the draft in the combustion area to pull combustion air and combustion gases through the heat exchanger. Typically, the induced-draft fan operates for a few minutes in a prepurge cycle to clear out old combustion gasses before the ignition process is attempted.	
Draft pressure switch, normally open Must close to indicate correct draft. The ignition process does not proceed if this switch does not close. These are usually normally open and must close to indicate draft.	
Hot surface igniter relay This is actually part of the furnace control board. It energizes to send voltage to the hot-surface igniter.	
Hot-surface igniter The hot-surface igniter is energized long enough for it to get hot, typically 30 seconds to a minute.	
Ignition trial: gas valve energizes The gas valve is energized for a short time, usually no longer than 3 seconds.	
Ignition trial flame rectification circuit The flame safety looks for a microamp signal on the flame sensor, indicating the presence of flames. If the signal is not seen in 2 to 3 seconds, the gas valve is shut down. Most furnaces will cycle through the prepurge to ignition trial several times attempting to light. If they don't light after four or five attempts, the heat circuit is locked out for a period of several hours.	
Indoor blower relay This is actually part of the furnace board. The furnace control board energizes the indoor blower after a time delay of 1.5 to 3 minutes to allow the heat exchanger to heat up.	
Indoor blower motor The indoor blower motor is energized to circulate warm air throughout the house	
W terminal de-energized, all for heat satisfied The thermostat quits sending 24 V to the W terminal once the temperature is satisfied	
Post-purge The induced-draft fan motor continues to operate for 1 to 2 minutes to purge the combustion chamber of any remaining combustion gases.	Heat exchanger cool down The indoor blower remains to get the remaining heat in the heat exchanger into the house.

Figure 92-4 Induced-draft gas furnace operating sequence.

OIL FURNACE OPERATING SEQUENCE		
Manual reset primary control safety Shuts down primary control if ignition is not achieved in time.		
Thermostat terminal R , Control Power, R must receive 24 V for unit to work. R connects 24 volts to W to start a call for heat.		
Thermostat terminal W , Heating W is energized when there is a call for heating.		Thermostat Terminal G , Indoor Fan In AUTO position G is NOT energized for heating. In ON position, G is energized all the time.
Auto reset primary limit The primary limit shuts down the flames if the heat exchanger area overheats.		Indoor fan relay Closes contacts when coil is energized.
Burner motor relay This is part of the furnace primary control. It energizes to operate the burner motor.		Run capacitor Required for fan operation.
Oil burner motor	Ignition transformer	Indoor blower motor
Turns on both the oil pump and the combustion air blower.	Creates the high-voltage spark to ignite the oil.	
Cad cell ignition check Cad cell sees the light of the flames and signals to primary control that ignition has occurred. If flames are not seen in 90 seconds, the primary control safety trips and shuts down the furnace.		
Indoor blower relay This is usually part of the primary control. The furnace primary control energizes the indoor blower after a time delay of 1.5 to 3 minutes to allow the heat exchanger to heat up.		
Indoor blower motor		
The indoor blower motor is energized to circulate warm air throughout the house.		
W terminal de-energized when call for heat satisfied The thermostat quits sending 24 V to the W terminal once the temperature is satisfied.		
Oil burner motor stops		
The burner motor stops.		
Indoor blower motor stops		
The indoor blower continues to operate for 2 to 3 minutes to remove the heat remaining in the heat exchanger.		

Figure 92-5 Oil-fired furnace operating sequence.

It takes very little time to check these items, and the most common problems can be traced to one of them. Further, if any of these are not correct, system performance tests will not produce accurate results.

92.8 COLLECTING OPERATIONAL DATA

The next step is to collect data that tell how the system is actually operating. Sources for the current system operational data include the homeowner, general observation, diagnostic boards, and system performance tests. All of these are not necessary in every situation, but service technicians typically use more than one of these methods to collect data about system operation. Remember that troubleshooting is a lot like solving a puzzle: the more clues you have, the easier it is to solve.

Homeowner Information

The homeowner can be a valuable source of information, but information gained from talking to homeowners should be verified because they may not always be able to make accurate statements based on their observations. Information from homeowners should be general, not specific. Do not ask the homeowner if the compressor is operating, as he or she may not know what a compressor is or where it is located.

Diagnostic Codes

Many systems now have electronic control boards with built-in diagnostics. The diagnostics typically consist of LEDs that flash a one- or two-digit code. The codes are typically listed in the manufacturer's service literature and frequently can also be found somewhere on the unit. The

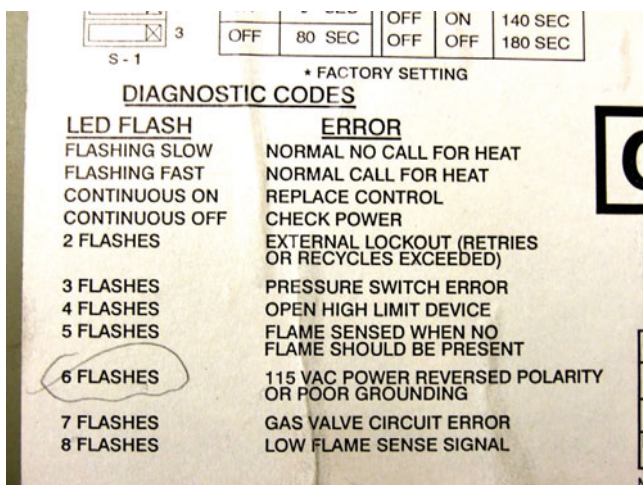

Figure 92-6 Typical ignition board fault code.

number of LED flashes corresponds to the code number. In Figure 92-6, three flashes (fault code 3), indicate “pressure switch error.” For two-digit codes there is a pause between the flashes representing the first digit and the flashes representing the second digit. The code then repeats. Some boards differentiate between the first and second digits by the length of the flashes; long flashes representing one digit and short flashes representing the other. For example, a

series of two long flashes and four short flashes would represent a code 24.

System Performance Tests

System performance tests provide more detailed information about how a system is operating. The specific tests will vary depending on the type of equipment being checked. Some common system performance tests include checks for refrigerant pressure, superheat, subcooling, temperature change, and electrical current draw. The purpose of these tests is to allow comparison between actual performance and factory-specified performance. Figure 92-7 shows system performance data for a water-source heat pump. System performance checks provide a more accurate picture of how well a system is performing than casual observation does. Rather than simply feeling the supply air to see if it is cool, measuring its temperature provides a quantifiable measurement. For systems that are checked regularly, recording this information provides a baseline to compare current and past system performance.

92.9 RECOGNIZING INCORRECT OPERATION

Troubleshooting often appears to begin at this step. Experienced technicians may already understand the system operation thoroughly, so the first step has essentially already been done ahead of time. An experienced

Figure 92-7 Water-source heat pump performance data.

technician can often quickly recognize incorrect operation in a system that they are already familiar with. However, comparing the actual operation to factory specifications is still the most accurate way to recognize incorrect operation. Collecting operational data is not always necessary initially. If a system is not operating at all, there is not a lot of useful data to collect. However, system performance data should be taken after getting the unit operating. Remember that the component or condition preventing unit operation may be another symptom, not the root cause of the problem.

92.10 TESTING TO ISOLATE THE CAUSE

Many people think of this part of the process as troubleshooting. Indeed, the majority of a technician's troubleshooting time is spent tracking down the cause of the problem. However, technicians should avoid the temptation to jump straight into solving a problem that is not clearly defined. Jumping straight to determining the cause can waste time by looking for the cause of nonexistent problems.

Proceed from General to Specific

Try to resist the temptation of starting immediately to diagnose specific components. The slowest way to solve a problem is by jumping from one component to the next looking for the specific cause before you have a good idea of exactly what the system is doing. First make sure you understand what the system is supposed to do. Next, determine what the system is actually doing, and then determine what it is doing incorrectly. Once you know what the system is doing wrong, start with more general investigations like system line voltage or control voltage.

The Process of Elimination

The key to determining the root cause in a reasonable amount of time is to follow a logical pattern of investigation and use the process of elimination. You should have a purpose for each test performed. For example, if a system is not operating at all, a logical question is whether it has voltage available. Taking a voltage reading at the power source will help decide where to look next. If no voltage is available, then the reason for the loss of power must be investigated. On the other hand, if voltage is present, then it would make sense to look at the controls. Each test should eliminate some avenues of investigation and help narrow the focus of further tests.

92.11 LOGICAL ELECTRICAL TROUBLESHOOTING PROCEDURE

Electrical problems are by far the most common problems encountered in the field. A general procedure for quickly isolating the cause of an electrical failure is to check the following:

1. Line voltage to the unit
2. Control voltage
3. Voltage to the component that is not functioning
4. Circuit to the component that is not functioning

Line Voltage to the Unit

A significant number of problems are solved at this point. If the system does not operate at all, check to see that it has the correct voltage. If a fuse is blown or a breaker is tripped, look for the reason. Overload devices can open because of reasons other than problems in the unit, like power interruptions. However, anytime a fuse is replaced or a breaker is reset, the operation of the system should be checked carefully. Before operating the system, check all major loads for shorts or grounds and check the main power wire connections. Run the system and check the amp draw on the circuit to the unit and at each major load.

Control Voltage

If a system has no control voltage, the controls cannot operate the system. Control voltage can be out because the part of the system that houses the transformer has no line voltage, or it can be an issue with the transformer that supplies the control voltage. If a low-voltage fuse is blown, or if the transformer needs replacing, be sure to look for shorts and grounds in the low-voltage components. Check the secondary voltage immediately after the fuse or transformer is replaced. If a short is causing the transformer to overheat, the secondary voltage will drop very low, possibly close to 0 V. The transformer cannot take this for more than a few seconds, so it must be recognized immediately. If there are no problems at power-up, monitor the secondary voltage while running the system through all its operating cycles.

Voltage to Nonfunctional Component(s)

If there are nonfunctional components and the system has both line voltage and control voltage, the next step is to determine if these components are receiving voltage. At this point, you are trying to determine if the problem is in the component or in the circuit to the component.

If the component is receiving the correct voltage and is not operating, the problem is most likely that component. However, be careful with single-phase motors. Most single-phase motors have some sort of starting components: run capacitor, start capacitor, or starting relay. Failure of the starting components will keep a single-phase motor from operating. It is more common for these starting components to fail than for the actual motors to fail.

Circuit to Nonfunctional Component(s)

If the nonfunctional component is not receiving voltage, the circuit to the component needs to be checked. Since you now know that the unit has both line voltage and control voltage and that the voltage is not getting to the inoperative component, it is logical to conclude that the problem is somewhere in the circuit to the component. You need to locate the break in the circuit. The most effective method of locating a break in a circuit is a technique called hopscotching.

92.12 HOPSCOTCHING

This technique works by starting at a point where there is correct voltage and moving one lead at a time from point to point in the circuit toward the nonfunctional load until the

voltage is lost. Most circuits put all the controls on one side of a load. Use the schematic diagram to identify all the controls in series with the load and the path that voltage takes to get to the load.

Place the leads at a point in the circuit before the controls, where the correct voltage will be read. Follow the schematic and move the meter lead on the control side of the circuit from one control to the next, checking the voltage in and out of the control. The voltage will drop to 0 immediately after the control that is opening the circuit.

Next, you need to determine why the control is open. For example, if the control is a pressure switch, check the system pressures. If the control is a relay, check to see if the relay coil is receiving voltage. If it is not receiving voltage, then you need to investigate the circuit to the coil using the same hopscotching technique. If the control is receiving the correct input and is not closing, it needs to be replaced.

For example, Figure 92-8 shows the low-voltage schematic for an air-conditioning unit with a contactor that is not closing. The contactor coil is shown in blue. Three controls are in series between the thermostat and the contactor

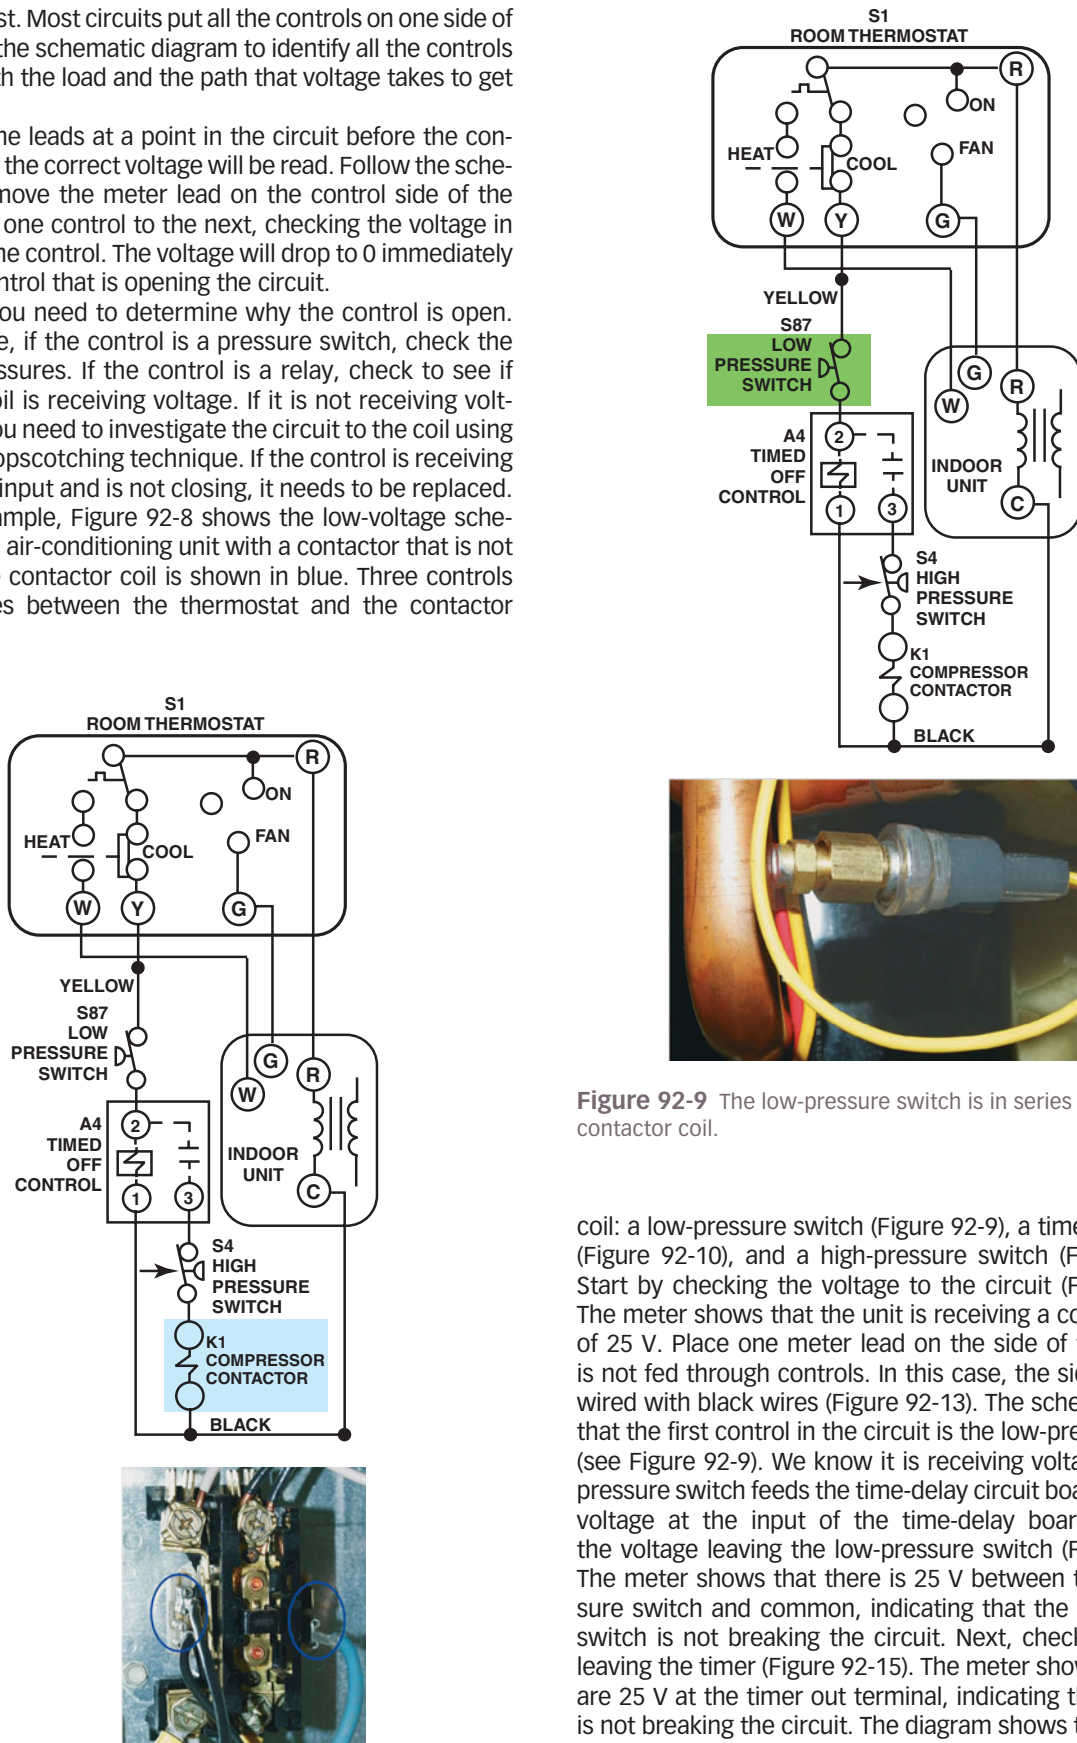

Figure 92-8 Schematic of low-voltage circuits in air-conditioning condensing unit.

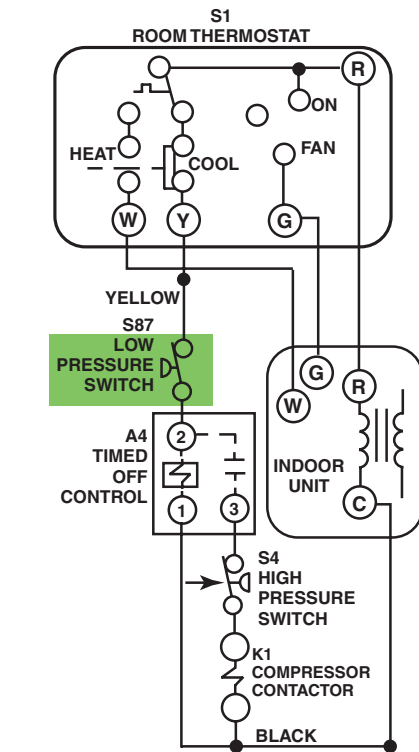

Figure 92-9 The low-pressure switch is in series with the contactor coil.

coil: a low-pressure switch (Figure 92-9), a timed off control (Figure 92-10), and a high-pressure switch (Figure 92-11). Start by checking the voltage to the circuit (Figure 92-12). The meter shows that the unit is receiving a control voltage of 25 V. Place one meter lead on the side of the load that is not fed through controls. In this case, the side of the coil wired with black wires (Figure 92-13). The schematic shows that the first control in the circuit is the low-pressure switch (see Figure 92-9). We know it is receiving voltage. The low-pressure switch feeds the time-delay circuit board. Checking voltage at the input of the time-delay board will check the voltage leaving the low-pressure switch (Figure 92-14). The meter shows that there is 25 V between the low-pressure switch and common, indicating that the low-pressure switch is not breaking the circuit. Next, check the voltage leaving the timer (Figure 92-15). The meter shows that there are 25 V at the timer out terminal, indicating that the timer is not breaking the circuit. The diagram shows that the high-pressure switch is next in the circuit (see Figure 92-11). The leads for the high-pressure switch are wired directly to the timer and the contactor coil. The meter reading drops to near

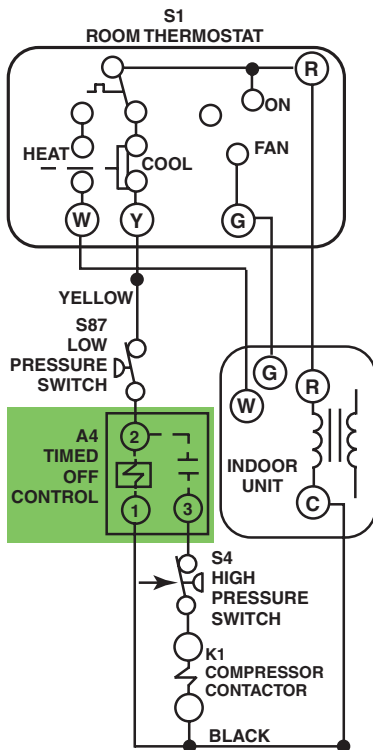

Figure 92-10 The timed off circuit board is in series with the contactor coil.

0 V when checking the voltage at the contactor coil, indicating that the high-pressure switch is open (Figure 92-16). The next step would be to check the system high-side pressure to determine whether the pressure switch should be open. If the system pressure is high, then the technician should look for causes of high discharge pressure.

92.13 REFRIGERATION CYCLE TROUBLESHOOTING

The first thing to check with any refrigeration problem is the flow across the evaporator and condenser. There is no point in taking pressure and temperature readings on a system that does not have the correct airflow or water flow across one of its coils. The majority of refrigeration problems can

Figure 92-11 The high-pressure switch is in series with the contactor coil.

be solved by establishing a proper flow across both the condenser and evaporator.

Once proper flow is established, system operating data can be collected. As always, the best benchmarks are those provided by the manufacturer. However, technicians should be able to recognize many common refrigeration cycle problems even without the manufacturer's data. Many problems can be identified by looking at these system performance indicators:

- Low-side pressure
- High-side pressures
- Suction-line temperature
- Discharge-line temperature
- Liquid-line temperature
- Air or water temperature rise across the condenser
- Air or water temperature drop across the evaporator

Four of the most important indicators require a comparison of data:

- Suction-line superheat
- Liquid-line subcooling

Figure 92-12 Checking the low-voltage control signal coming into the unit.

Figure 92-13 The common side of low voltage can be read at the common side of the contactor coil.

- Condenser temperature difference (delta T)
- Evaporator temperature difference (delta T)

Suction-line superheat is the difference between the actual suction-line temperature and the refrigerant saturation temperature. The saturation temperature is obtained from the suction pressure using a refrigerant pressure-temperature chart. Liquid-line subcooling is the difference between the saturation temperature obtained from the discharge pressure using a pressure-temperature chart and the actual liquid-line temperature.

Figure 92-14 Checking the voltage leaving the low-pressure switch and entering the timed off board.

Figure 92-15 Checking the voltage leaving the timed off board and centering the high-pressure switch.

Figure 92-16 Checking the voltage leaving the high-pressure switch and entering the contactor coil.

TECH TIP

Many technical manuals use the word *delta* when talking about the difference in a condition. For example, delta-T is used for temperature difference and delta-P is used for pressure difference. Sometimes the Greek letter delta is used, which looks like a triangle: Δ . So temperature difference is abbreviated as ΔT and pressure difference is abbreviated as ΔP . These are simply shorthand ways of writing temperature difference or pressure difference.

The condenser temperature difference is simply the difference between the temperature of the air or water entering the condenser and the temperature of the air or water leaving the condenser. The evaporator temperature difference is the difference between the temperature of the air or water entering the evaporator and the temperature of the air or water leaving the evaporator.

The chart in Figure 92-17 summarizes the effect common problems will have on the important refrigeration cycle indicators. There are no numbers on the chart, only arrows. The arrows show if a system performance indicator will increase or decrease from normal as a result of a particular problem. The technician still must know what normal is to use the chart.

92.14 RECOMMENDING CORRECTIVE ACTION

The technician's job is to solve problems, so the customer should be offered at least one solution to the problem at hand. Sometimes the corrective action is obvious. If a part has failed, it must be replaced. However, make sure that you solve the problem and not the symptoms. If a part has failed because of abuse or lack of maintenance, be sure to include correcting the cause of the failure as part of the solution.

When possible, it is best to keep customers informed as you proceed. They will have a much easier time accepting a large repair bill if they had an opportunity to choose not to implement the repair. Again, understanding how the system works and being able to logically explain your solution are crucial at this point. If the solution being proposed involves replacing parts, be prepared to explain why each of the parts is necessary. If the solution involves customer education, be patient. It is never helpful to be condescending toward customers.

92.15 USING MANUFACTURERS' TROUBLESHOOTING CHARTS

Most manufacturers supply some form of troubleshooting chart in the service manuals for their equipment. These tend to take three general forms: logical troubleshooting flowcharts, lists of common symptoms and causes, and references to fault codes provided by diagnostic LEDs on the system controls.

Logic Flowcharts

A logic flowchart provides pass/fail tests to help guide the technician in using the process of elimination to locate the cause of a system malfunction (Figure 92-18). These charts

Problem	Discharge Pressure	Subcooling	Condenser Delta T	Suction Pressure	Superheat	Evaporator Delta T	Compressor Amps
Low flow of evaporator air or water	↓	↑	↓	↓	↓	↑	↓
Dirty evaporator	↓	↑	↓	↓	↓	↑	↓
liquid line restriction	↓	↑	↓	↓	↑	↓	↓
Underfeeding expansion device	↓	↑	↓	↓	↑	↓	↓
Undercharge	↓	↓	↓	↓	↑	↓	↓
Low-capacity compressor	↓	↑	↓	↑	↑	↓	↓
Low flow of condenser air or water	↑	↓	↑	↑	↓	↓	↑
Dirty air-cooled condenser	↑	↓	↑	↑	↓	↓	↑
Scaled water cooled condenser	↑	↓	↓	↑	↓	↓	↑
Overcharge	↑	↑	↓	↑	↓	↓	↑
Overfeeding expansion device	↑	↓	↓	↑	↓	↓	↑

Figure 92-17 Refrigeration cycle troubleshooting chart.

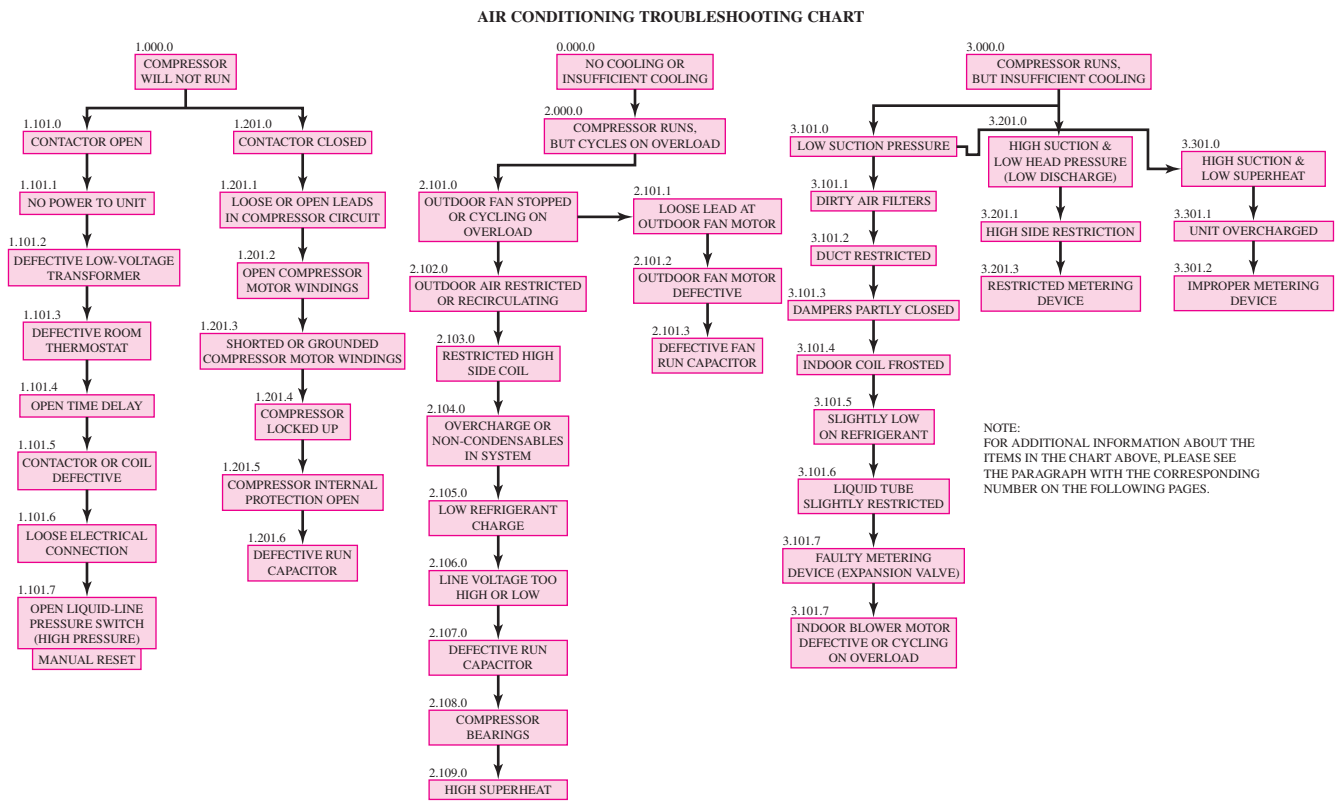

Figure 92-18 Example of a troubleshooting logic flowchart.

WATER SOURCE HEAT PUMP TROUBLESHOOTING CHART		
PROBLEM	CAUSE	CORRECTION
Nothing operates in any thermostat setting	No power to unit	Check circuit breaker or fuses
	Defective control transformer	Replace defective transformer
	Loose connection	Repair connection
	Defective thermostat	Replace thermostat
Unit short cycles	Thermostat location	Move thermostat
Blower operates but compressor does not operate	Defective compressor overload	Replace (if external)
	Defective compressor contactor	Replace
	Supply voltage too low	Check power wire size
	Defective compressor capacitor	Replace capacitor
	Defective windings	Replace compressor
	Limit switches open	Check cause and replace
Insufficient system capacity	Dirty air filter	Replace air filter
	Blower RPM too low	Increase blower RPM
	Leaky duct work	Repair and/or seal ductwork
	Low refrigerant charge	Locate leak, recover charge, repair leak, evacuate and recharge system
	Restricted expansion valve	Replace expansion valve
	Defective reversing valve	Replace reversing valve
	Thermostat located in supply air	Move thermostat
	Undersized system	Perform load calculation
	Insufficient water flow	Increase water flow
	Scaled or fouled water coil	Clean or replace water coil
	Water temperature outside of manufacturer's specified operating limits	Correct water temperature
High pressure switch open or high head pressure	Inadequate water flow	Increase water flow
	Water too hot	Decrease water temperature
	Dirty or fouled water coil	Clean or replace water coil
	Inadequate airflow	Increase airflow
	Dirty air filter	Replace air filter
	Overcharged with refrigerant	Recover charge
	Defective pressure switch	Replace pressure switch
	Non-condensables in system	Recover refrigerant, evacuate and recharge
Low pressure switch open or low suction pressure	Inadequate airflow	Increase airflow
	Dirty air filter	Replace air filter
	Inadequate water flow	Increase water flow
	Water too cold	Increase water temperature
	Undercharged with refrigerant	Add refrigerant charge
	Defective pressure switch	Replace pressure switch
	Restricted expansion valve	Replace expansion valve

Note: Items in blue apply only to cooling cycle, items in red apply only to heating cycle.

Figure 92-19 Example of a troubleshooting systems list.

can be especially useful for determining if proprietary control boards are functioning properly. The danger of these troubleshooting aids is that answering one question incorrectly can send you off in an entirely incorrect direction. Technicians who have too little knowledge of how a system actually works may not understand why tests are being performed or even exactly how to perform them. Incorrect readings cause misinterpretation of the chart.

Symptom Lists

Many manufacturers provide a list of common symptoms and their most common causes (Figure 92-19). These troubleshooting aids can help speed up diagnosis of common problems. These are generally easier for people to follow and require less testing. However, it is not really possible to make a complete list of all possible symptoms, or even a complete list of all the possible causes of any particular symptom. Another issue is the temptation to simply go down

the list of causes for a particular symptom. If more than one component can cause the same symptom, multiple components may be replaced by someone who is just running the list and does not really know how to check each component.

Fault Code Reference List

Most units today employ some type of electronic control. Many of these have built-in diagnostics. Typically, these diagnostics will tell the technician what the control is "thinking." A list of fault conditions is typically located in the service manual (Figure 92-20) and also frequently on the unit (Figure 92-21). The explanation can be a short description, such as "open pressure switch," or it can be a more detailed explanation of the problem including a fault history of the system.

Technicians need to understand the limitations of on board diagnostics. On-board diagnostics can only report issues for which there are inputs. All the board knows is that an input is correct or incorrect. The accompanying chart can

Figure 92-20 Fault code from a service manual.

FURNACE FAULT CODES		
Red LED	Green LED	Indication
	Simultaneous Slow Flash	Power on Normal operation. No call for heat. Also signaled during cooling and continuous fan.
	Simultaneous Fast Flash	Normal operation with a call for heat.
	Alternating Slow Flash	Flame not sensed after ignition attempt.
	Alternating Fast Flash	Broken igniter or igniter circuit.
Fast Flash	Slow Flash	Main power polarity reversed or improper main ground.
Slow Flash	Fast Flash	Low flame signal.
Slow Flash	On	Primary or auxiliary limit switch open.
Off	Slow Flash	Draft pressure switch fault.
Slow Flash	Off	Flame sensed without gas valve energized.
On	Slow Flash	Roll out switch open.
On	On	Control board wired incorrectly or defective.
Off	On	Control board wired incorrectly or defective.
On	Off	Control board wired incorrectly or defective.

Figure 92-21 Fault code located on an equipment panel.

suggest what the cause is, but it does not really know. Verifying the cause is still the service technician’s job. Although diagnostics greatly simplify locating system malfunctions, they do not replace understanding how a system operates or knowing how to diagnose faulty components.

UNIT 92—SUMMARY

Troubleshooting is the process of identifying the problems, determining their cause, and correcting the cause of the problem. Technicians should view units as systems, keeping

in mind the interrelationship between the electrical, refrigeration, and airflow system components. Troubleshooting can be broken down into the following steps:

- Understanding system operational sequence
- Preliminary system inspection
- Collecting operational data
- Recognizing what is operating incorrectly
- Testing to isolate the cause
- Recommending corrective action

Technicians must understand exactly how equipment operates so they can analyze the cause of improper operation. Understanding the operating sequence of the most common types of systems is important. Sources of information on system operation include the manufacturer’s installation and operation and manuals, unit wiring diagrams, unit charging charts, and general textbooks. Preliminary system checks should include checking the thermostat setting, air filter, airflow and/or water flow, line voltage, and control voltage. Operational data can come from the homeowner, general observation, diagnostic boards, and system performance tests. Troubleshooting logic flowcharts, common symptom lists, and diagnostic codes can all be helpful in identifying the cause of system malfunction. The hopscotching technique is useful for identifying the problem in a malfunctioning electrical circuit. When troubleshooting the refrigeration cycle in a system, key performance indicators include the following:

- Low-side pressure
- High-side pressures
- Suction-line temperature
- Discharge-line temperature
- Liquid-line temperature

- Air or water temperature rise across the condenser
- Air or water temperature drop across the evaporator
- Suction-line superheat
- Liquid-line subcooling
- Condenser delta T
- Evaporator delta T

The technician should be able to explain to the customer exactly what is causing the problem and recommend a solution.

WORK ORDERS

Service tickets 9201–9204 all start with the same symptoms, but they each have a different root cause. The beginning of each call starts out as follows:

A customer calls because his air-conditioning system is not cooling properly. The system is operating when the technician arrives, and the technician notices that the condensing fan motor outside is running but that the compressor is not running. The compressor line-voltage wires on the contactor have the correct voltage. The compressor shell is very hot. The technician turns off the power to the unit and measures the resistance of the compressor terminals. There is no continuity between common and either run or start, but there is continuity between start and run. This indicates that the internal overload is open.

Each service ticket picks up from this point.

Service Ticket 9201

Customer Complaint: Poor Cooling

Equipment Type: R-410a Residential Split-System Air Conditioner

... The condenser coil appears clean. The technician checks the compressor starting components and finds that the compressor run capacitor is open. The run capacitor is replaced. The compressor starts and runs correctly after it cools down and the internal overload resets. The technician checks the system performance against the manufacturer's specifications on the service panel to verify that it is operating correctly.

Service Ticket 9202

Customer Complaint: Poor Cooling

Equipment Type: R-410a Residential Split-System Air Conditioner

... The condenser coil appears clean. The technician checks the compressor starting components and finds that they are all good. Next, the technician checks the system pressure and finds the equalized pressure is

100 psig. The technician concludes that the system is undercharged, leading the compressor to overheat. A leak inspection reveals a leak at the mechanical fitting on the suction line. The technician tightens this fitting, stopping the leak. The unit is charged according to the manufacturer's performance chart after the compressor cools and is able to operate.

Service Ticket 9203

Customer Complaint: Poor Cooling

Equipment Type: R-410a Residential Split-System Air Conditioner

... The condenser coil appears to be clogged with debris. The technician concludes that poor condenser air-flow has caused the compressor to overheat, turns off the power to the unit, and cleans the condenser coil. The compressor starts and runs correctly after it cools down and the internal overload resets. The technician checks the system performance against the manufacturer's specifications on the service panel to verify that it is operating correctly.

Service Ticket 9204

Customer Complaint: Poor Cooling

Equipment Type: R-410a Residential Split-System Air Conditioner

... The condenser coil appears clean. The technician checks the compressor starting components and finds that they are all good. Next, the technician checks the system pressure and finds the equalized pressure is 200 psig. The technician decides that the system will have to operate to make any further diagnosis. The compressor starts and runs after it cools down and the internal overload resets. The high-side pressure climbs quickly to close to the manufacturer's specification. The low side, however, drops to around 50 psig, much lower than the manufacturer's specification. The superheat and subcooling are both high, and the air temperature exchange across the condenser is lower than normal. The technician begins looking for a temperature drop in the liquid line that would indicate a restriction. None is found. The expansion device is an expansion valve. The technician removes the thermal bulb and holds it, looking for a change in the low-side pressure or superheat. There is no change. The technician concludes that the thermostatic expansion valve is underfeeding, causing the compressor to overheat. The refrigerant is recovered, the expansion valve changed, and the system is evacuated and recharged according to the manufacturer's specifications. The technician operates the system and compares the system performance to the manufacturer's specifications to verify that the system is performing correctly.

Service Ticket 9205**Customer Complaint: No Cooling****Equipment Type: Residential Packaged Heat Pump**

... A customer complains that he has no cooling. The technician arrives, makes sure the thermostat is set to Cool, and checks the line voltage to the unit. The line voltage is 0 V. The technician finds a blown fuse in the outdoor disconnect switch. Next, all major loads are checked for shorts and grounds. None are found. The technician notes that the fuses in the disconnect box are one-time fuses and replaces both fuses with time-delay fuses. The unit comes on and runs after the fuses are replaced. The technician checks the system amp draw and the amp draw of each component and finds them at or below the data plate specifications. Next, the system performance is checked against the manufacturer's specifications to verify correct operation.

Service Ticket 9206**Customer Complaint: No Cooling****Equipment Type: Residential Packaged Heat Pump**

... A customer complains that they have no cooling. The technician arrives, makes sure the thermostat is set to cool, and checks the line voltage to the unit. The line voltage is 240 V. The technician checks the control voltage and finds 0 V. The technician finds 24 V fuse to the R terminal is blown. The fuse is replaced and it immediately blows again. The technician starts checking the low voltage controls for shorts and finds that the compressor contactor coil has a resistance reading of $\frac{1}{2}$ ohm. The contactor is replaced and the system is turned on again. This time the system starts and operates. Next, the system performance is checked against the manufacturer's specifications to verify correct operation.

Service Ticket 9207**Customer Complaint: Noisy Unit****Equipment Type: R-22 Residential Split System Air Conditioner**

... A customer calls complaining about his condensing unit making a lot of noise. The customer states that all his neighbors have the same systems, and they are all noisy. However, he cannot stand the noise any longer and is ready to change out the unit if necessary. The customer also asks for the "extra cooling" option, explaining that he paid the original contractor \$100 to add extra refrigerant to improve the system's performance. The technician explains that adding extra charge does not help the unit cool better. If anything, it makes it cool worse. The technician checks the system performance characteristics and finds that both pressures are high, the superheat is essentially 0°F, and the subcooling is 30°F. The technician suspects that the system charge

was not done correctly at installation and elects to start from scratch. So all the charge is recovered, the system evacuated, and a full charge weighed in according to the manufacturer's data plate information, including line allowances. The system starts and runs much more quietly, and the pressures fall to within the manufacturer's specifications.

UNIT 92—REVIEW QUESTIONS

1. List some common questions customers ask service technicians.
2. Explain what is meant by a systems approach to troubleshooting.
3. Give an example of an airflow problem that can look like a refrigerant charge problem if a service technician is only looking at system pressures.
4. List the stages of troubleshooting.
5. What checks are typically performed during the preliminary inspection?
6. What should a service technician do if there is a blown fuse in the unit disconnect switch during the preliminary inspection?
7. What should a service technician do if there is a blown fuse in series with the low-voltage side of the transformer?
8. Outline a method of isolating an electrical fault using the process of elimination.
9. Describe the process of hopscotching.
10. Using the logic flowchart in Figure 92-18, what is the first condition listed to check for a compressor that will not run when the contactor is closed?
11. Using the symptoms list in Figure 92-19, what possible causes are listed for a unit that experiences high-pressure-switch tripping only during the cooling cycle?
12. Using the chart in Figure 92-20, what conditions cause both lights to display an alternating fast flash?
13. Using the air-source heat pump sequence chart in Figure 92-2, list the devices in order that control the outdoor fan.
14. Using the chart in Figure 92-17, what problems can cause both a high superheat and a high subcooling?
15. Using the induced-draft sequence chart in Figure 92-4, what should be checked if the induced-draft fan comes on but the igniter is never energized?
16. List some resources the air-conditioning technician can use to learn about the system operational sequence.
17. List some sources the air-conditioning technician can use to get system operational data.
18. Using Figure 92-7, what should the approximate suction pressure be for a system operating in heating with an entering water temperature of 50°F and a water flow of 5 GPM?
19. Why are diagnostic codes not always able to identify the system problem?
20. Why should service technicians be familiar with company pricing policies?

Glossary

A Spanish version of the Glossary is available in MyHVACLab.

A Coil Evaporator consisting of two coils joined together forming the shape of the letter A.

Absolute Humidity The actual amount of moisture in a given volume of air.

Absolute Pressure Gauge pressure plus atmospheric pressure.

Absolute Temperature Temperature measured from absolute zero.

Absolute Zero Temperature at which all molecular motion ceases (−460°F and −273°C).

Absorbent Substance that has the ability to take up or absorb another substance.

Absorber A device containing liquid for absorbing refrigerant vapor or other vapors.

Absorption Diffusion of one substance into the inner composition of another substance.

Absorption Chiller Device used to produce chill water using the absorption cycle.

Absorption Cycle Refrigeration cycle based upon the absorption of the refrigerant by a chemical substance rather than by mechanical compression.

Absorption Refrigerator A refrigerator that utilizes the principles of the absorption cycle.

Accessible Hermetic A hermetically sealed unit that can be opened for repair and maintenance, also referred to as semi-hermetic.

Accumulator A storage vessel located in the suction line before the compressor. Used to limit liquid refrigerant return to the compressor and store excess refrigerant in the heating mode.

Acetylene Gas commonly used with oxygen for brazing and soldering.

ACR Tubing Air conditioning and refrigeration tubing sealed on each end to keep the tubing clean and dry.

Activated Alumina An aluminum oxide desiccant used in refrigeration system driers to absorb moisture.

Activated Carbon Specially processed carbon commonly used to clean air.

Active Refrigerant Recovery Device A self contained recovery unit that is not an integral part of the refrigeration system.

Active Solar System A system designed to utilize solar energy.

Actuator A device used to convert fluid power, thermal energy, and electrical energy into mechanical motion.

Adiabatic Compression Compressing refrigerant gas without removing or adding heat.

Adsorbent Substance that has the property to hold molecules of fluids without causing a chemical or physical change.

Air The fluid surrounding us composed mainly of oxygen and nitrogen.

Air-Acetylene Brazing torch that draws in the surrounding air rather than requiring a separate oxygen supply.

Air Binding A condition in which a bubble or other pocket of air is present in a pipeline that prevents the desired flow in the pipeline.

Air Break An inverted opening placed in a chimney to prevent a downdraft from affecting the furnace flame.

Air Changes The amount of air leakage through a building in terms of the number of building volumes exchanged.

Air Cleaner A filtration system used to remove airborne impurities.

Air Coil A refrigeration heat exchanger that has air passing across its outer surface.

Air Conditioner Device used to control temperature, humidity, cleanliness, and movement of air in conditioned space.

Air Conditioning The process to control temperature, humidity, cleanliness, and movement of air in conditioned space.

Air Conditioning Heating and Refrigeration Institute (AHRI) A national trade association representing manufacturers of over 90% of U.S.-produced central air conditioning, gas appliances, and commercial refrigeration equipment.

Air Cooled Condenser A heat exchanger that uses air passing across it to condense refrigerant from vapor to liquid.

Air Core Solenoid A solenoid that has a hollow center.

Air Curtain Forced air used to shield the food product in an uncovered display case.

Air Cushion Tank (see Expansion Tank)

Air Defrosting A defrost method of shutting the unit off while allowing the warm air to circulate.

Air Diffuser An air register designed to distribute air in a specific arrangement.

Air Friction Chart A chart used for sizing round ducts.

Air Gap The air space between the rotating and stationary components of a motor or generator.

Air Handler A unit housing a blower and heating/cooling coils that is used for delivering air to a space.

Air Heat Exchanger A heat exchanger that allows for air to be drawn across its exterior surface.

Air Loop The ducted air side on a heat pump system.

Air Pressure Switch Measures air pressure drop across an outdoor heat pump coil to determine frost build-up.

Air Sensor Installed in air handlers to measure conditions such as temperature, pressure, velocity, and humidity.

Air Shutter An adjustable shutter on the primary air openings of a burner that is used to control the amount of combustion air.

Air Source Heat Pump Heat pump that transfers heat from outdoor air to an indoor air circulation system.

Air Standard The ASHRAE standard designation for dry air at 70°F and atmospheric pressure.

Air-to-Air Heat Pump (see Air Source Heat Pump)

Air Vent A valve installed at the high points in a hot water system to remove air from the system.

Air Washer Filtration of air using water or other liquid.

Aldehyde A class of compounds that can be produced during incomplete combustion of a fuel gas.

Algae A light to dark green plant growth that can develop in water systems.

- Alkylbenzene** A synthetic oil compatible with CFC and HCFC refrigerants.
- Allen Head Screw** Screw with recessed head designed to be turned with a hex shaped wrench.
- Alternating Current (AC)** Current that reverses polarity or direction with regular frequency. It can be single phase, two phase, three phase, or polyphase.
- Alternative Refrigerant** A replacement refrigerant that is different from the existing system refrigerant.
- Alternator** A machine that converts mechanical energy into alternating current.
- Altitude** The measured distance above sea level.
- Altitude Adjustment** Thermostat adjustment to account for changes in elevation dependent on geographical location.
- Ambient Compensator** An electronic device that provides enough heat to cycle the refrigeration unit when ambient temperatures are low.
- Ambient Temperature** Temperature of the air that surrounds an object.
- American National Standards Institute (ANSI)** Institute that determines refrigeration standards along with ASHRAE.
- American Society of Heating, Refrigeration, and Air Conditioning Engineers (ASHRAE)** Its membership is composed of thousands of professional engineers and technicians from all phases of the HVACR industry. ASHRAE also creates equipment standards for the industry.
- American Society for Testing and Materials Engineers (ASTME)** Society that, in addition to materials testing, determines wind and rain infiltration standards.
- American Standard Pipe Thread** Identifies the standard pipe thread size encountered in the field for installation purposes.
- American Wire Gauge (AWG)** A system of numbers that designate cross-sectional area of wire. As the diameter gets smaller, the number gets larger, for example, AWG #14 = 0.0641 in, AWG #12 = 0.0808 in.
- Ammeter** An electric meter used to measure current.
- Ammonia** A widely used refrigerant for large commercial systems due to its high latent heat value.
- Amperage** The measured flow of electrical current.
- Ampere** Unit of electric current equivalent to the flow of one coulomb per second.
- Ampere Turn (AT) (NI)** Unit of magnetizing force produced by a current flow of one ampere through one turn of wire in a coil.
- Amplitude** The maximum instantaneous value of alternating current or voltage. It can be in either a positive or negative direction.
- Analog Electronic Device** A device that delivers a modulated signal.
- Analog Signal** A modulated signal as compared to a digital signal, which is binary.
- Analog VOM** A volt-ohm meter using a needle measurement scale rather than a digital display.
- Anemometer** Instrument for measuring the flow rate of air.
- Aneroid Barometer** An instrument used for measuring barometric pressure.
- Angle Valve** A valve that is constructed with a 90° bend.
- Angle of Lag or Lead** Phase angle difference between two sinusoidal waveforms having the same frequency.
- Annealing** Process of heat treating metal to obtain desired properties of softness and ductility.
- Annual Fuel Utilization Efficiency (AFUE)** A furnace efficiency comparison for consumers.
- Anode** The positive electrode in an electrolytic cell.
- Anticipator** A heater used to adjust thermostat operation to produce a closer temperature differential than the mechanical capability of the control.
- Antifreeze Solution** A mixture of glycol and water with a freezing point below 32°F.
- Approach** Term used for cooling water towers to determine effectiveness. A measure of the cooling air ambient wet bulb compared to the temperature of the cooling water.
- Approach Temperature** Chilled water leaving temperature compared to refrigerant temperature.
- Arcing** Sparking discharge between two electrodes or contacts.
- Armature** The moving or rotating component of a motor, generator, relay, or other electromagnetic device.
- ASME** American Society of Mechanical Engineers.
- Aspect Ratio** Ratio of length to width of a rectangular duct.
- Aspirating Psychrometer** A device that draws in a sample of air to measure for humidity.
- Aspiration** To draw a fluid by creating a suction.
- Atmospheric Dust Spot Efficiency** A measure of the ability for a filter to remove atmospheric dust from a test sample of air.
- Atmospheric Pressure** The envelope of atmospheric gases creating a pressure equal to approximately 14.7 psi at a temperature of 70°F at sea level.
- Atom** Smallest particle of an element.
- Atomic Weight** The number of protons in an atom of a material.
- Atomize** Process of changing a liquid to a fine spray.
- Atomization** (see Atomize)
- Atomizing Humidifier** A humidifier that supplies finely atomized water into the airstream.
- Attenuate** Decrease or lessen in intensity.
- Auger** Rotating device resembling a huge corkscrew used in ice machines.
- Authorized Dealer** A dealer authorized to install heat pumps by the manufacturer.
- Automatic Changeover Thermostat** A thermostat that automatically changes modes dependent on the room temperature.
- Automatic Defrost** System of removing ice and frost from evaporators automatically.
- Automatic Expansion Valve (AEV)** Pressure controlled valve used as a metering device.
- Automatic Pumpdown System** A system designed to pump down refrigerant to the receiver prior to shutting down.
- Autotransformer** A transformer in which both primary and secondary coils have turns in common. Stepup or stepdown of voltage is accomplished by taps on a common winding.
- Auxiliary Drain Pan** Located beneath the evaporator coil to collect and drain away water that condenses from the air.

Azeotrope Two or more refrigerants mixed together by the refrigerant manufacturer that have the combined properties of a single refrigerant.

B Vent Double walled vent pipe used for gas furnace applications.

BW Vent Double walled vent pipe used with wall type gas furnaces.

Back Electromotive Force (BEMF) Voltage generating effect of an electrical motor's rotor.

Back Pressure Pressure in the low side of the refrigeration system. Also called low side pressure or suction pressure.

Back Seat The position of a service valve that is all the way counterclockwise or fully open.

Bacteria Microscopic organisms found almost everywhere; while some types can be useful, other types can cause disease.

Baffle Similar to a damper used to regulate the flow of a fluid.

Balance Fitting A pipe fitting or valve designed so that its resistance to flow may be varied. This type of fitting is used to obtain the desired flow rate through parallel circuits.

Balance Point The outdoor temperature at which the heating capacity of a heat pump in a particular installation is equal to the heat loss of the conditioned area. Below the balance point, supplementary heat is needed to maintain indoor comfort.

Balance Point, Initial The outdoor ambient temperature at which the heating capacity of the heat pump only balances the heat loss of the conditioned area.

Balance Point, Second The outdoor temperature at which the heating capacity of the heat pump plus the auxiliary heat capacity balances the heat loss of the conditioned area.

Balanced-Port TEV A thermostatic expansion valve that compensates for wide variations in high to low side pressure and evaporator loads.

Ball Check Valve A check valve that uses a ball against a seat as a shut-off means.

Ball Valve A valve in which modulation or shut-off is accomplished by a one quarter turn of a ball that has an opening through it.

Bar One bar is 100 kilopascals (kPa) with 101.3 kPa equal to standard atmospheric pressure.

Barometer Instrument for measuring atmospheric pressure.

Base Semiconductor terminal.

Baseboard A terminal unit resembling the base trim of a house.

Bath A container holding a liquid where a component can be washed or heated.

Battery Two or more primary or secondary electrically interconnected cells.

Baudelot Cooler Heat exchanger in which water flows by gravity over the outside of the tubes or plates.

Bearing Ball bearings are used in pumps and motors to hold the rotating shaft in alignment with the casing.

Bellows Corrugated cylindrical container that moves as pressures change.

Bellows Seal A crankshaft seal made tight by a bellows arrangement.

Belly-Band-Mount Motor An electric motor held in place with a metal strap.

Belt A flexible material used to connect rotating shafts through a pulley arrangement, such as a motor driving a fan.

Bending Spring Coil spring that is used to keep a tube from collapsing while being bent.

Bio-aerosol An airborne microbial contaminant, such as a virus, bacteria, fungus, or algae.

Bimetal Strip Two dissimilar metals with unequal expansion rates fused together.

Blast Freezer A unit that deep freezes the product faster than conventional freezers.

Bleeding Slowly draining pressure from a system.

Bleed Off The continuous or intermittent wasting of a small fraction of the water in the basin of a cooling tower to prevent the buildup of scale-forming minerals.

Bleed Valve Valve that permits a minimum fluid flow when valve is closed.

Blend A mixture of two or more refrigerants.

Blocked Suction A method for unloading a reciprocating compressor.

Blowdown Draining a controlled amount of water from a cooling water tower to reduce the level of dissolved solids.

Blown Building insulation can be applied to a structure using this method. A melted fuse can be considered blown.

Blower A centrifugal fan.

Boiler A furnace that generates either hot water or steam.

Boiler, High Pressure A boiler that operates at a pressure higher than 15 psig.

Boiler, Low Pressure A boiler that operates at a pressure below 15 psig.

Boiler Horsepower The equivalent evaporation of 34.5 lb of water per hour at 212°F. This is equal to a heat output of $970.3 \times 34.5 = 33,475$ Btu/hr.

Boiling Point Temperature at a given pressure at which a fluid changes from a liquid to a gas.

Boiling Temperature Temperature at which a fluid changes from a liquid to a gas.

Bonnet The sheet metal chamber in a furnace where heat collects.

Booster Pump A second pump used to raise the pressure in the system higher than created by the first pump.

Boot Connection between a floor register and a branch duct.

Bore Inside diameter of a cylindrical hole.

Bourdon Tube Thin walled tube of circular shape that tends to straighten as pressure inside is increased.

Boyle's Law Law stating the pressure-volume relationship of gases.

Brazing Soldering with a filler material whose melting temperature is higher than 840°F.

Break Electrical discontinuity in the circuit generally resulting from the operation of a switch or circuit breaker.

Breaker (see Circuit Breaker)

Breaker Strip Strip of plastic used to cover the joint between the outside case and the inside liner of a refrigerator.

Breeching Transition piece located between furnace and stack.

Bubble Point The formation of bubbles in a saturated liquid refrigerant zoetrope will begin at this temperature.

Building Related Illness (BRI) Health disorders linked to the environment of modern airtight buildings.

Built Up System Unit is not packaged but instead the individual components (condenser, compressor, etc.) are installed together at the job site.

Brine Water saturated with a chemical such as salt.

British Thermal Unit (Btu) The amount of heat required to raise the temperature of 1 lb of water (about one pint) by 1°F.

Bulb Used as a sensing element for valves and controls.

Bull Head The installation of a pipe tee in such a way that water enters (or leaves) the tee at both ends of the run (the straight through section of the tee) and leaves (or enters) through the side connection only.

Bunsen Burner A gas burner in which combustion air is premixed with the gas supply within the burner body before the gas burns at the burner port.

Burner A device for the final conveyance of gas, or a mixture of gas and air, to the combustion zone.

Burnout Accidental passage of high voltage through an electrical circuit or device that causes damage.

Burr Raised edges left behind from cutting tubing or a pipe. This burr must be removed before installation.

Butane A highly flammable, colorless, odorless, easily liquefied gas.

Butterfly Valve A valve with a handle that can be positioned 90° to be either parallel (open) or perpendicular (closed) to the fluid flow.

Bypass A connection that diverts the fluid flow around a valve or component.

Cadmium Cell A device whose resistance changes according to the amount of light sensed.

Calibrate To adjust an indicator so that it correctly indicates the variable sensed.

Calorie Heat required to raise the temperature of 1g of water 1°C.

Calorimeter A device for measuring the heat of chemical reactions.

Cam A projection on a rotating disc that can be used to operate defrost timers as the cam slowly turns.

Capacitance A measure of the amount of energy stored by a capacitor.

Capacitive Reactance The capacitive electrical impedance opposing the alternating current in a circuit.

Capacitor Type of electrical storage device used in starting and/or running circuits on many electric motors.

Capacitor Start Motor (CSR) A single-phase motor that has a capacitor in series with the start winding.

Capacity The rating of a unit generally based on size, power, and refrigerant amount.

Capillary Attraction The ability of one substance to draw another substance into it.

Capillary Tube A fixed restriction pressure reducing device. Usually consists of lengths of small inside diameter tubing. The flow restriction produces the necessary reduction in pressure and boiling point of the liquid refrigerant before entering the evaporator.

Capillary Tube System A refrigeration unit that utilizes a capillary tube type of flow control device.

Carbon Dioxide (CO₂) A nontoxic product of combustion.

Carbon Dioxide Indicator Device used to measure carbon dioxide levels.

Carbon Filter Activated charcoal filter used for adsorption purposes.

Carbon Footprint The total set of greenhouse gas emissions caused by an organization, event, product or person.

Carbon Monoxide (CO) A chemical resulting from incomplete combustion. It is odorless, colorless, and toxic.

Carbon Neutrality Refers to achieving net zero carbon emissions by balancing a measured amount of carbon released with an equivalent amount.

Cascade System One having two or more refrigerant circuits, each with a compressor, condenser, and evaporator, where the evaporator of one circuit cools the condenser of the other (lower temperature) circuit.

Cathode Electrode through which positive electric current flows.

Cavitation Vapor bubbles forming in a liquid region due to a drop in pressure that creates turbulence.

Celsius The metric system temperature scale.

Cellulose Used as an environmentally preferable material for building insulation.

Centigrade An earlier name for the Celsius scale.

Centimeter Metric unit of linear measurement, equals 0.3937 in.

Central Air Conditioning Air is treated at a central station and then distributed to the conditioned spaces by a series of ducts.

Central Station The equipment required for treating the air is all located together at one location.

Centrifugal Compressor Compressor that compresses gaseous refrigerants by centrifugal force.

Centrifugal Force The outward force created by the circular motion of an object.

Centrifugal Pump A pump with a rotating impeller that utilizes centrifugal force to pump a liquid.

Centrifugal Switch A switch that opens or closes due to the action of centrifugal force.

Ceramic Ignitor Ignitor used for gas stoves and heaters.

Change of State (see Phase Change)

CFM Cubic feet per minute (ft³/min).

Charge The amount of refrigerant in a system.

Charging Cylinder A device for charging a predetermined weight of refrigerant into a system.

Charging Scale Digital scale that measures the weight of refrigerant in a cylinder.

Charging the Loop Filling the earth loop with the correct mixture and purging all the air from the loop.

Charles' Law The ideal gas law.

Check Valve A flow control valve that permits flow in one direction only.

Chemical Refrigeration (see Absorption Cycle)

Chill Factor (see Wind Chill Factor)

Chiller Refrigeration system designed to cool water, glycol, or brine.

Chilled Water System The series of pumps and heat exchangers used to deliver chilled water to a conditioned space.

Chimney Stack used for venting hot flue gases from a boiler or furnace.

- Chimney Connector** Connecting pipe to connect the furnace to the chimney.
- Chimney Effect** The tendency of air or gas in a duct or other vertical passage to rise when heated.
- Chimney Flue** Chimney stack.
- Chlorinated Polyvinyl Chloride (CPVC)** A thermoplastic used for hot and cold water pipes.
- Chlorofluorocarbon (CFC)** Refrigerant composed of chlorine, fluorine, and carbon.
- Circuit** A tubing, piping, or electrical wire installation that permits flow from the energy source back to energy source.
- Circuit Breaker** A device that senses current flow and opens when its rated current flow is exceeded.
- Circuit, Parallel** (see Parallel Circuit)
- Circuit, Pilot** A device used to initiate a circuit.
- Circuit, Series** (see Series)
- Circulator** A pump used for hydronic heating systems.
- Clamp-on Ammeter** Current measuring device that is not connected directly to the circuit but instead temporarily clamps around the electrical wire.
- Clearance Space** Amount of access space required on all sides and above and below an installed unit.
- Clean Room** Found in semiconductor manufacturing plants to maintain a perfectly clean environment.
- Clearance** Space in cylinder not occupied by the piston at the end of the compression stroke.
- Climate** Weather conditions for a specific geographical region established over long periods of time.
- Climate Control** HVAC is often referred to as a method of climate control.
- Closed Circuit** Completed path for current flow with no open switches.
- Closed Circuit Cooling Tower** The process cooling fluid is completely isolated from the atmosphere.
- Closed Loop** Any cycle in which the primary medium is always enclosed and repeats the same sequence of events.
- Closed-Loop Control Configuration** A sensor monitors the output and provides feedback to maintain setpoint conditions.
- Closed-Loop Heat Pump** A geothermal heat pump that circulates a glycol solution through a ground coil.
- Clutch, Magnetic** Transmits torque and speed without contact.
- Clutch, Centrifugal** The driving shaft nested inside the driven shaft uses centrifugal force for engagement.
- Coaxial Fitting** A fitting that connects to a single port of a hot water storage tank. Or, tube in a fitting. The hot water goes through the tube into the tank, and the cold water comes out of the fitting surrounding the tube.
- Coaxial Heat Exchanger** A spiral shaped heat exchanger consisting of an inner and outer tube for counterflow applications.
- Code** Local, state, and national rules and regulations.
- Coefficient of Conductivity** Thermal conductivity of a substance (k).
- Coefficient of Expansion** Change in length per degree of temperature change of a substance.
- Coefficient of Performance (COP)** A ratio calculated by dividing the total heating capacity provided by the refrigeration system, including circulating fan heat but excluding supplementary resistance heat (Btu/hr), by the total electrical input (watts) $\times 3.412$.
- Cogeneration** Combined heat and power.
- Coil** A wound conductor that creates a strong magnetic field when current passes through it.
- Coil, Device Subcooler** A section in the outdoor evaporator coil used to increase the liquid subcooling during the cooling mode as well as act as an extra defrost surface during the defrost mode.
- Coil, Inside** The coil located in the inside portion of the heat pump system. Performs as the evaporator in the cooling mode and the condenser in the heating mode.
- Coil, Outside** The coil located in the outside portion of an air-to-air heat pump system. Performs as an evaporator in the heating mode and as the condenser in the cooling mode.
- Cold** The absence of heat.
- Cold Anticipator** (see Cooling Anticipator)
- Cold Junction** The part of the thermoelectric system that absorbs heat.
- Cold Trap** Used with vacuum pumps to collect condensation.
- Collector** Semiconductor terminal.
- Combined Annual Efficiency (CAE)** Annual performance of combination appliances such as space and water heaters.
- Combustible Liquids** Class II and Class III liquids with closed cup flash points at or above 100°F.
- Combustion** The rapid oxidation of fuel gases accompanied by the production of heat.
- Combustion Air** Air supplied for the combustion of a fuel.
- Combustion Analyzer** Device used for analysis of flue gases for optimizing combustion efficiency.
- Combustion Products** Constituents resulting from the combustion of a fuel gas with the oxygen in air, including the inerts, but excluding excess air.
- Comfort** Those conditions that are most suitable for human well being.
- Comfort Chart** Chart used in air conditioning that shows the dry bulb temperature and humidity for human comfort.
- Comfort Zone** The temperature and humidity range within which one is comfortable.
- Commercial Buildings** Such buildings as stores, shops, restaurants, motels, and large apartment buildings.
- Commercial System** Systems designed for nonmanufacturing business establishments.
- Commutator** A ring of copper segments insulated from each other and connecting the armature and brushes of a motor or generator. It passes power into or from the brushes.
- Compound Gauge** Pressure gauge that has scales both above and below atmospheric pressure.
- Compound Pump** A two stage pump.
- Compound Refrigerating System** System that has several compressors in series.
- Compression** A reduction of gas volume resulting in an increase in pressure.
- Compression Gauge** A gauge used to measure compression pressure.
- Compression Ratio** The absolute discharge pressure divided by the absolute suction pressure for a compressor.

Compression Ring Piston ring closest to the cylinder head on a reciprocating compressor.

Compression Tank (see Air Cushion Tank)

Compressor The pump of a refrigerating mechanism that draws a vacuum or low pressure on the cooling side of refrigerant cycle and squeezes or compresses the gas into the high pressure or condensing side of the cycle.

Compressor Crankcase Location for the crankshaft and oil sump.

Compressor Displacement The volume discharged by a compressor in one rotation of the crankshaft.

Compressor, External Drive A compressor that requires a crankshaft seal because it is externally coupled to a motor.

Compressor Head (see Cylinder Head)

Compressor, Hermetic A sealed unit with the compressor and motor located within the same casing.

Compressor, Multiple Stage Compressor with more than one stage of compression.

Compressor Oil Cooler Heat exchanger used to cool the oil in a compressor crankcase.

Compressor, Open (see Compressor, External Drive)

Compressor, Reciprocating Compressor that uses pistons driven by a crankshaft.

Compressor, Rotary Screw Compressor that utilizes two meshed rotating positive-displacement helical screws.

Compressor Seal Leakproof seal between crankshaft and compressor body.

Compressor Shaft Seal (see Shaft Seal)

Compressor, Single Stage Compressor with only one stage of compression.

Condensate Water that has condensed on the surface of a cooling coil.

Condensate Drain Trap A pipe arrangement that provides a water seal in the drain line to prevent airflow through the drain line.

Condensate Pan A pan located under an evaporator to collect condensate from the coil and carry it to the drain line.

Condensate Pump Device used to remove fluid condensate.

Condensation Liquid that forms when a vapor is cooled below its condensing temperature or dew point.

Condense The action of changing a saturated vapor to a saturated liquid.

Condenser The part of the refrigeration system that receives the high pressure superheated vapor from the compressor and extracts the heat in the vapor reducing it to a high pressure saturated liquid.

Condenser, Air Cooled A heat exchanger that transfers heat energy from the refrigerant vapor to air.

Condenser Fan A fan used to deliver air across the surface of an air cooled condenser.

Condenser Flooding Condenser containing excessive liquid refrigerant.

Condenser, Liquid Cooled A heat exchanger that transfers heat energy from the refrigerant vapor to the liquid heat sink.

Condenser Water Pump A device used to supply cooling water to the condenser.

Condensible A gas that can be easily converted to liquid form.

Condensing Boiler Boiler where the flue gas is allowed to drop below the dew point temperature and condense.

Condensing Furnace (see Condensing Boiler)

Condensing Pressure The refrigerant pressure inside the condenser coil.

Condensing Temperature The temperature at which a vapor changes to a liquid at a given pressure.

Condensing Unit The portion of the refrigeration system that converts high pressure superheated vapor to high pressure saturated liquid. Commonly called the high side.

Conductance, Thermal (C) The time rate of heat flow per unit area through a material.

Conduction, Thermal Particle to particle transmission of heat.

Conductivity The ability of a substance to allow the flow of heat or electricity.

Conductor Material or substance that readily passes electricity.

Connected Load The sum of the capacities or continuous ratings of the load-consuming apparatus connected to a supplying system.

Connecting Rod The part of a compressor that connects the piston to the crankshaft.

Console An interface to operate computers and control systems.

Constant A known and unchanging value.

Constrictor Tube or orifice used to restrict flow.

Contact The part of a switch or relay that carries current.

Contact A device for making or breaking load carrying contacts by a pilot circuit through a magnetic coil.

Contaminant A substance (dirt, moisture, etc.) foreign to refrigerant or refrigerant oil in a system.

Continuous Absorption Cycle An absorption cycle that uses a limited amount of heat with no moving parts.

Continuous Operation Unit that is always running.

Contractual Agreement Agreed to by both parties and legally binding.

Control Switches and other devices to run HVAC/R equipment.

Control Motor Motor used to control an action such as the positioning of a damper.

Control, High Pressure Shuts down the unit if the high pressure setpoint is reached.

Control Loop Control system with sensors and feedback.

Control, Low Pressure A pressure operated control connected to the suction side of the refrigeration system to prevent unit operation below a set pressure or coil operating boiling point.

Control Module Component that contains the control system inputs and outputs.

Control Point The actual value as compared to the setpoint.

Control, Refrigerant A device used to provide the necessary pressure reduction of the liquid refrigerant to obtain the proper boiling point of the refrigerant in the evaporator.

Control System System used to manage, command, direct, or regulate other devices.

Control, Temperature A device that uses changes in temperature to operate contacts in an electrical circuit.

Control Valve Valve used for directing flow.

Controlled Environment (see Climate Control)

Controlled Medium The conditioned air or water distributed through an HVAC/R system.

Controller Measures the difference between sensed output and desired output and initiates a response to correct the difference.

Convection Transfer of heat by means of movement of a fluid, either liquid or air.

Convection, Forced Transfer of convective heat assisted by a pump or fan rather than natural circulation.

Convection, Natural Transfer of convective heat by natural circulation with warm air rising and cold air falling.

Conversion Factor Constant value used to change from one scale to another such as from Celsius to Fahrenheit.

Cooler A walk-in or reach-in refrigerated compartment.

Cooling Anticipator A resistor in a room thermostat that causes the cooling cycle to begin prematurely.

Cooling Coil An evaporator coil.

Cooling Tower Device that cools water by evaporation in air. Water is cooled to the wet bulb temperature of air.

Copper Plating Electrolysis process that leads to copper deposits on the compressor internals.

Core, Air (see Air Core Solenoid)

Core, Magnetic (see Solenoid)

Core Valve (see Schrader Valve)

Corrosion The breakdown of material such as the weakening of iron due to oxidation known as rust.

Cotter Pin Split type fastener also called a cotter key or split pin.

Coulomb An electrical unit of charge; one coulomb per second (C/s) equals one ampere (A) or 6.25×10^{23} electrons past a given point in 1s.

Counter EMF Counterelectromotive force. The EMF induced in a coil that opposes applied voltage.

Counterflow Two liquids and/or vapors flowing in directions opposite to each other.

Coupling Device used to connect two shafts together.

Cracking a Valve Opening a valve a small amount.

Cradle-Mounted Motor A motor cradled on each end and held down with a bracket.

Crankcase Heater A heating device fastened to the crankcase or lower portion of the compressor housing intended to keep the oil in the compressor at a higher temperature than the rest of the system to reduce the migration of the refrigerant.

Crankcase Pressure Regulating Valve (CPR) Device to limit the compressor suction pressure to reduce the load at startup.

Crankshaft Converts rotating motion to reciprocating motion through the connecting rod to the piston.

Crankshaft Seal Leakproof joint between crankshaft and compressor body.

Crank Throw Location where the connecting rod is attached to the crankshaft.

Creosote The buildup of carbon deposits in chimneys from wood-burning fires.

Crisper The enclosed vegetable compartment in a refrigerator.

Critical Pressure The vapor pressure at the critical temperature.

Critical Temperature The temperature above which liquid and gas phases do not exist.

Cross-Charged A TEV sensing bulb charged with a fluid that is different from the refrigerant used in the system.

Cryogenic Temperatures typically below -238°F .

Cryogenic Fluid Liquid nitrogen and liquid helium are commonly used in cryogenic applications.

Cryogenic Food Freezing Liquid nitrogen is used in blast freezing or immersion freezing systems.

Cryogenics The branches of physics and engineering that involve the study of very low temperatures.

Crystallization A highly concentrated brine solution that precipitates as salt.

Cupronickel An alloy of copper and nickel that does not corrode in seawater.

Current The flow of electrons through a conductor.

Current Relay Opens or closes contacts with a change in current flow through it.

Current Limiting Fuse Opens the circuit if the current is above the setpoint.

Current Transformer Provides current in its secondary winding proportional to the current flow through its primary winding.

Customer Relations The evaluation of the technician by the customer as a result of the job performance and attitude.

Cut In The temperature or pressure at which an automatic control switch closes.

Cut Out The temperature or pressure at which an automatic control switch opens.

Cycle A repeated series of events from start to end, such as the refrigeration cycle.

Cylinder, Compressor Compression chamber that houses the piston in a reciprocating compressor.

Cylinder Head Part that encloses compression end of compressor cylinder.

Cylinder, Refrigerant Rigid container holding refrigerant that may be of the disposable type or reusable type, such as a recovery cylinder.

Cylinder Unloading Method of reducing compressor load by cutting out individual cylinders.

Cylindrical Commutator Armature for a motor.

Dalton's Law Law of partial pressures.

Damper Movable plate or louver for controlling airflow.

Damper, Return Air Positioned to control air flow through the return air duct.

Damper, Outdoor Air Positioned to control airflow through the outdoor air duct.

DC Motor Direct current motor.

Dead Band A range of temperature in a heating/cooling system in which no heating or cooling is supplied.

Decibel Unit used for measuring relative loudness of sounds.

Deck, Cold Air directed over a cooling coil located in separate cool air duct for a large zone system.

Deck, Hot Air directed over a heating coil located in separate hot air duct for a large zone system.

Dedicated Geothermal Well Water is drawn from the top of the well and returned to the bottom of the well. The well supplies only the heat pump.

Deep Vacuum A vacuum of 500 microns or less.

Defrost Control A control system used to detect frost or ice buildup on the outside coil of an air-to-air heat pump

during the heating mode and causes the system to reverse in order to remove the frost or ice from the coil.

Defrost Cycle Refrigerating cycle in which evaporator frost and ice accumulation is melted.

Defrosting Method of removing frost and ice from an evaporator coil.

Defrosting Evaporator An evaporator that utilizes hot gas defrost.

Defrost Mode The portion of system operation when the evaporator frost or ice is removed.

Defrost Timer A device connected into the electronic control system that controls the frequency and duration of the defrost operating mode.

Degreaser Cleaning solvent used to remove grease.

Degreasing Using degreaser to remove grease buildup.

Degree Day Unit that represents one degree of difference from a standard average outdoor temperature of one day.

Dehumidify Lowering air temperature below its dew point to remove moisture.

Dehumidifier Device such as a cooling coil used for dehumidification.

Dehydrate To remove water in all forms from a material or system.

Dehydrated Oil Moisture free oil.

Dehydrator Removes moisture in a refrigeration system and is often referred to as a drier.

Deice To remove ice such as in defrosting.

Deice Control (see Defrost Control)

Delta Connection The connection in a three phase system in which terminal connections are triangular, similar to the Greek letter delta (Δ).

Delta-P Change in pressure.

Delta-T Change in temperature.

Delta Connected Motor (see Delta Connection)

Demand The size of any load generally averaged over a specified interval of time.

Demand (Billing) The demand upon which billing to a customer is based.

Demand Meter An instrument used to measure peak kilowatt hour consumption.

Density Weight per unit volume.

Deodorizer Substance used to inhibit the growth of bacteria that causes odors.

Department of Energy (DOE) Name for the government agency in North America devoted to national energy.

Department of Transportation Name for the government agency in North America devoted to transportation.

Desert Bag Watertight bag that may be used for storage. A bag used to keep water cool in the desert.

Desiccant Substance used to collect and hold moisture.

Desiccant Drier Usually located in the liquid line, a drier charged with desiccant.

Design Load The amount of heating or cooling required to maintain inside conditions when the outdoor conditions are at design temperature.

Design Pressure Rated pressure the system is normally designed to operate at.

Design Temperature Difference The difference between the design indoor and outdoor temperatures.

Design Water Temperature Difference The difference between the temperature of the water leaving the unit

and entering the unit when the system is operating at design conditions.

Desuperheater A heat exchanger in the hot gas line between the compressor discharge and reversing valve. Used to heat domestic water by removing the superheat from the hot refrigerant vapor.

Detector, Leak A test instrument used to detect and locate refrigerant leaks.

Detent Allows for a controlled hesitation in movement.

Dew Water that has condensed out of air.

Dew Point Temperature at which water vapor begins to condense out of air. Air at the dew point—100% relative humidity—is referred to as saturated air.

Diagnostics Methodical identification of symptoms to identify problems with operating equipment.

Diagnostic Thermostat A thermostat that can receive input to diagnose problems.

Diaphragm Flexible membrane.

Diaphragm Valve The valve stem acts on a diaphragm to open or close the valve.

Dielectric An insulator or nonconductor.

Dies (Thread) Tool used to cut external threads.

Differential As applied to controls, the differential between the cut in and cut out temperature or pressure setpoints of a control.

Diffuser Air distribution outlet designed to direct airflow into a room.

Diffuse Radiation Solar radiation reaching the earth's surface after having been scattered by molecules in the atmosphere.

Digital Electronic Devices Devices that send or receive bit stream digital signals.

Digital Electronic Signal A waveform that switches between two voltage levels representing two states (0 and 1).

Digital Volt Ohm Milliammeter (VOM) A multimeter with a digital output.

Dilution Air Air that enters a draft hood and mixes with the flue gases.

Diode A device that will carry current in one direction but not the reverse direction.

Dual Inline Pair Switch (DIP) A small low amperage single-pole, double-throw switch used in electronic circuits.

Direct Current (DC) Electric current that flows only in one direction.

Direct Digital Control (DDC) The ability to control HVAC devices via microprocessors.

Direct Drive Compressor Compressor directly connected and driven at motor speed.

Direct Drive Motor Motor directly connected to device it is driving.

Direct Expansion Evaporator The primary refrigerant expands and absorbs heat from the air as opposed to an indirect expansion system that uses a secondary refrigerant such as chill water.

Direct Return A two pipe system in which the first terminal unit taken off the supply main is the first unit connected to the return main.

Direct Spark Ignition (DSI) The gas burner is lit by a direct spark rather than a pilot.

Direct Vent Flue gases can be vented directly outside the building without the use of a chimney.

Discharge Pressure Refrigerant pressure on the high side at the compressor outlet of a system.

Discharge Valve A valve located directly at the outlet of the compressor.

Disconnecting Switch A knife switch that opens a circuit.

Discus Compressor A compressor with discus valve design to allow for capacity modulation to reduce cycling.

Discus Valve A valve designed to allow for less clearance volume vapors to be trapped when the piston is at top dead center.

Dispensing Freezers Units that process and freeze previously pasteurized product, such as soft ice cream.

Displacement The total volume of refrigerant that a compressor can draw in during the intake stroke.

Distributed Controls The controls are not in a central location but rather distributed throughout the system.

Distributor Allows for distribution of refrigerant to individual refrigerant circuits in an evaporator coil.

District Heating and Cooling A system for distributing heat generated in a centralized location for residential and commercial use.

Disturbed Earth Effect Denotes the heat content change that affects the earth's temperature by the addition or removal of heat energy by the heat pump system.

Diverter Tee Fitting used for a hydronic system to direct water through a terminal unit branch circuit.

Dome Hat Compressor housing for a hermetically sealed refrigeration unit.

Domestic Hot Water Heated water used for cooking, washing, and so on.

Domestic Geothermal Well Water is drawn from the top of the well. Only the water from the heat pump is returned to the bottom of the well. The difference is used for building requirements.

Door Heater A heater located around the opening of a refrigerator door to prevent the door from freezing closed.

Downflow Furnace Furnace where the return air enters at the top, flows down through the heat exchanger, and exits out the bottom.

Double Pole Switch Simultaneously opens and closes two connections of a circuit.

Double Thickness Flare Tubing end that has been formed into a two-wall thickness.

Dowel Pin Pin pressed through two assembled parts to ensure accurate alignment.

Downdraft Downward flow of flue gas.

Draft Gauge Instrument used to measure air pressure.

Draft Indicator Instrument used to measure chimney draft.

Draft Regulator Device used to automatically control chimney draft.

Drier A substance or a device used to absorb moisture within a refrigeration system.

Drift Entrained water carried from a cooling tower by wind.

Drilled Port Burner A burner in which the ports have been formed by drilled holes.

Drilled Well A water supply for a geothermal water source heat pump.

Drip Pan Pan shaped panel or trough used to collect condensate from evaporator coil.

Drip Proof Motor A motor typically designed for outdoor use or a wet environment.

Drive Clip Steel fastener for connecting ductwork.

Dry Bulb Temperature The actual (physical) temperature of a substance. Usually refers to air.

Dry Cell Battery Common standard battery with a paste low-moisture electrolyte as compared to a wet cell type.

Dry Ice Solid carbon dioxide.

Dry System Refrigerant is metered into the evaporator coil rather than flooding the coil.

Dry Well A water return for a geothermal water source heat pump open loop.

Dual Pressure Regulator A high and low pressure control mounted together.

Duct Round or rectangular sheet metal or fiberglass pipe that carries the air between the conditioning unit and the conditioned area.

Duct Sweeper A cleaning tool used to remove dirt and debris from the inside of air ducts.

Dust Mites Microscopic bug often found in bedding and one of the most common allergens that trigger asthma.

Dynamometer Device for measuring power.

E Symbol for volts. From the term "electromotive force."

Earth Coupled Heat Pump Geothermal heat pump.

Earth Temperature, Minimum (T) The lowest temperature the earth will become in the winter season. Used for heat pump design. Will vary with location and weather conditions.

Eccentric A circle or disk mounted off center on a shaft.

Economizer, Air Conditioning Multiple flash chamber for air conditioning chiller designed to gain efficiency.

Economizer, Air Supply Adjusts for optimum outside air supply designed to maintain maximum efficiency.

Economizer, Evaporator Heat exchanger used to reduce flash gas through the metering device.

Eddy Currents Circulating flow of current within a conductor that can generate heat.

Effective Area The actual opening in a grill or register through which air can pass. The effective area is the gross (overall) area of the grill face minus the area of the deflector vanes or bars.

Effective Latent Heat (see Net Refrigeration)

Effective Temperature Calculated nonmeasured temperature based upon temperature, humidity, and air movement.

Effectiveness, Absorption Systems Method to evaluate absorption systems using heat input and cooling effect.

Efficiency, Electrical A percentage value denoting the ratio of power output to power input.

Ejector A venturi arrangement used as a pump with no moving parts.

Electric Defrosting An electric resistance strip heater attached to the evaporator coil used for defrosting.

Electric Field A magnetic region in space.

Electric Forced Air Furnace Return air is blown across electric resistance strip heaters.

Electric Heating A heating system that uses electric resistance elements as the heat energy source.

Electric Heating Element A unit consisting of resistance wire, insulated supports, and connection terminals for connecting wire to a source of electrical power.

Electric Hydronic Boiler Electric resistance heating elements used to heat water.

Electric Water Valve Electrically operated valve to control water flow.

Electrical Circuit Electrical wire installation that permits flow from the energy source back to energy source.

Electrical Erasable Programmable Read-Only Memory (EEPROM) Memory used in computers and electronic devices to store small amounts of data.

Electrical Power Measured in units of watts, equal to voltage \times amperage.

Electrical Resistance The degree to which an object opposes the flow of electric current through it.

Electrical Shock Contact with a voltage source allowing current to flow through the body.

Electricity The presence and flow of an electric charge.

Electrodes Used with high voltage applications for lighting oil and gas burners.

Electrolyte A solution of a substance (liquid or paste) that is capable of conducting electricity.

Electrolytic Capacitor Capacitor using a paper spacer soaked in electrolyte in one of its plates.

Electromagnet A magnet created by the flow of electricity through a coil of wire.

Electromagnetic Energy Energy derived from an electromagnet.

Electromechanical Controls Mechanical movement controlled through electrical input or motors.

Electromotive Force (EMF) The difference in potential or voltage of electrical energy between two points.

Electron Subatomic particle that carries a negative electric charge.

Electronic Charging Scale (see Charging Scale)

Electronic Circuit Board Printed board used to support and connect electronic solid state components.

Electronic Controls Control systems utilizing electronic circuit boards with solid state components.

Electronic Expansion Valve Electronically controlled, electrically operated type of valve.

Electronic Leak Detector An electronic instrument that measures the changes in electron flow across an electrically charged gap that indicates the presence of refrigerant vapor molecules.

Electronic Relay Electronic switch such as a Triac.

Electronics Field of science dealing with electronic devices and their uses.

Electronic Sight Glass Signals when system is low on refrigerant.

Electronically Commutated Motor (ECM) Brushless motor relying on an external power drive for commutation.

Electrostatic Filter Type of filter that gives particles of dust electric charge.

Embrittlement The loss of elasticity of a material, making it brittle.

End Bell End structure of electric motor that usually holds motor bearings.

End-Mount Motor Motor held in place at the motor housing end.

Endplay Slight movement of shaft along a center line.

Endothermal Chemical reaction where heat is converted to chemical bond energy.

Energized Having current flow.

Energy The ability to do work.

Energy Efficiency Ratio (EER) The comparison of the heat transfer ability of a refrigeration system and the electrical energy used as expressed in Btu/hr per watt. A ratio calculated by dividing the cooling capacity in Btu per hour (Btu/hr) by the power input in watts at any given set of rating conditions, expressed in Btu/hr per watt.

Energy Management System of computer-aided tools to monitor and control HVAC functions most efficiently.

Energy Management Control System (see Energy Management)

Energy Recovery Ventilator (ERV) Air-to-air heat exchanger installed in a duct system to gain efficiency.

Energy Star Government sponsored program designed to save consumers money and protect the environment through energy-efficient products and practices.

Energy Utilization Index (EUI) Comparison of energy usage within different areas of a building.

Enthalpy Heat content of a refrigerant, usually with respect to a reference point (Btu/lb).

Entropy Energy that cannot be used for external work.

Environment The surrounding conditions.

Environmental Protection Agency (EPA) Agency of the federal government responsible for safeguarding the natural environment.

Epoxy A synthetic plastic adhesive usually composed of two parts, the resin and the hardener.

Equalizer Tube Device used to maintain equal pressure or equal liquid levels between two containers.

Equivalent Length Calculated nonmeasured piping length taking into account friction losses.

Error Codes Code numbers used with control system to indicate faults.

Ester Lubricant Synthetic refrigeration oil.

Ethane Colorless and odorless gas used as a refrigerant in cryogenic refrigeration systems.

Eutectic Solution used for cold storage within evaporator coils.

Eutectic Point Temperature at which eutectic changes from liquid to solid.

Eutectic Solution Mixture of two solids so that the melting point is as low as possible.

Evacuate To remove water in all forms from a material or system.

Evacuation Removal of air, noncondensable gases, and moisture from a refrigeration system.

Evaporation A term used to describe the changing of a liquid to a vapor by the addition of heat energy. Change from liquid to vapor at a relatively slow rate.

Evaporative Condenser A device that uses a water spray to cool a condenser.

Evaporative Cooling The use of a water mist or spray to cool the air.

Evaporative Humidifier Addition of moisture to the airstream using a water mist or spray.

Evaporator Part of a refrigerating mechanism in which the refrigerant vaporizes and absorbs heat.

Evaporator Coil (see Evaporator)

Evaporator, Dry Type An evaporator into which refrigerant is fed from a pressure reducing device.

Evaporator Fan Fan that moves air through the evaporator.

Evaporator, Flooded An evaporator containing liquid refrigerant at all times.

Evaporator Pressure Regulator (EPR) Device used to regulate and control evaporator pressure.

Excess Air Air that is in excess of the required amount for complete combustion of a fuel gas.

Exfiltration Outward flow of air from an occupied area through openings in the building structure.

Exhaust Opening Any opening through which air is removed from a space.

Exhaust Valve Discharge valve for a positive displacement compressor.

Exothermal Chemical reaction where heat is released.

Expansion Joint A fitting or piping arrangement designed to relieve stress caused by expansion of piping.

Expansion Tank A closed tank that allows for water expansion without creating excessive pressure.

Expansion Valve A device in a refrigerating system that maintains a pressure difference between the high side and the low side.

Expendable Refrigerant System System that discards the refrigerant after it has evaporated.

Explosion Proof Motor Nonsparking motor designed to operate in explosive locations.

Extended Surface Heat transfer surface, one side of which is increased in area by the use of fins.

External Drive (see Compressor, External Drive)

External Equalizer A pressure connection from an area below the diaphragm of a thermostatic expansion valve and the outlet of an evaporator.

External Motor Protection Overload mounted on the outside of a motor.

Fahrenheit The common scale of temperature measurement in the English system of units.

Fail-Safe Designed to ensure safety of the unit in the event a component fails to operate.

False Defrost The system goes into the defrost mode even if the outdoor has no frost or ice buildup.

Fan A radial or axial flow device using rotating blades for moving air.

Fan Coil A terminal unit consisting of a finned tube coil and a fan in a single enclosure.

Fan Relay Relay used to start and stop a fan.

Farad The base unit of measurement for capacitance. Since a farad is a very large unit, a much smaller unit is usually used. (See Microfarad)

Faraday Experiment An experiment on electromagnetic induction.

Fast Acting Fuse A fuse that opens the circuit immediately if the rated current is exceeded.

Feedback The transfer of energy output back to input.

Feedback Control System Closed loop system with sensors that provide feedback based upon the setpoint.

Feet of Head (ft HD) The term used to designate the flow resistance the pump must overcome to deliver the required amount of liquid. 2.307 ft HD = 1 psig.

Female Thread A thread on the inside of a pipe or fitting.

Ferrous Objects made of iron or steel.

Fiberduct Duct made from fiberglass.

Fiberglass Fine glass fiber and resin composite.

Field The space involving the magnetic lines of force.

Field Pole Located as part of the motor stator winding.

Fill Honeycomb material for cooling water towers to slow the fall of water and increase surface exposure.

Film Factor Value representing resistance to heat transfer through the surface film of a material.

Filter-Drier A combination refrigerant drier and filter in one component.

Filter A device for removing foreign particles from vapor or liquid.

Fin Comb Comblike device used to straighten the metal fins on coils.

Finned-Tube Evaporator Tube type evaporator with attached fins to increase surface area and heat transfer.

Firepot Refractory-lined combustion chamber.

Fixed-Bore Device Refrigerant metering device with fixed orifice openings.

Fixed Resistor A resistor in which the value does not change.

Fire Tube Boiler A steel boiler in which the hot gases from combustion are circulated through tubes that are surrounded by water.

Flake Ice Small hard bits of ice ideally suited for any "contact" presentation, such as displaying fish at the supermarket.

Flame Detector The components of a flame detection system that detects the presence or absence of a flame.

Flame Impingement Excessively wide or jagged burner flame making contact with the side walls of a furnace.

Flame Rectification AC is converted to DC by the flame of a gas furnace.

Flame Sensing Element A device that uses heat, infrared, optical, rectification, rectifying photo cell, or ultraviolet light to detect a flame.

Flammability The ease at which a substance will ignite.

Flapper Valve A lightweight reed type valve hinged on one end allowing it to flap open and closed.

Flare An angle formed at the end of a tube.

Flare Nut Fitting used to clamp the tubing flare against another fitting.

Flashback The movement of the gas flame down through the burner port upon shutdown of the gas supply.

Flash Gas Vapor that is produced by the boiling of liquid refrigerant as it passes through the metering device.

Flash Point Temperature at which an oil will give off sufficient vapor to support a flame.

Flash Weld A resistance or spot weld where metal sections under pressure are fused together by electrical current.

Flexible Duct Designed to allow for some movement and bending to accommodate installation.

Flexible Lines Lines designed to accommodate bending.

Float Valve Type of valve that is operated by a sphere that floats on the liquid surface and controls the level of liquid.

Floating Head Pressure (see Head Pressure, Control)

Floc Point The temperature at which the wax in an oil will start to separate from the oil.

Flooded System Type of refrigerating system in which liquid refrigerant fills the evaporator.

Flooding Condition used to describe excessive liquid refrigerant in the evaporator or condenser.

Fluorescent Capable of emitting fluorescence such as in lighting.

Flow Check Piston Fixed orifice metering device with a piston assembly serving as a check control for reverse flow.

Flow Hood A direct reading instrument that measures air quantity in cubic feet per minute (CFM) out of or into a duct system.

Flow Meter Instrument used to measure the volume of a liquid flowing through a pipe or tube in quantity per time (gallons per minute, pounds per hour, liters per minute, etc.).

Flow Switch An automatic switch that senses fluid flow.

Flue A passage in the chimney to carry flue gas.

Flue Gases Products of combustion and excess air.

Fluid Substance in a liquid or gaseous state.

Flushing the Loop Forcing liquid through the loop at sufficient velocity to remove all forms of foreign material and air.

Flux Brazing, Soldering Substance applied to surfaces to be joined to free them from oxides.

Flux, Electrical The electric or magnetic lines of force in a region.

Flux, Magnetic Lines of force of a magnet.

Foaming Formation of foam in an oil refrigerant mixture due to rapid evaporation of liquid refrigerant entrained in the oil.

Foot of Water A measure of pressure. One foot of water is the pressure created by a column of water 1 ft high. This is equal to 0.433 psig.

Foot Pound Unit of work.

Force A push or pull which will cause an object to begin moving.

Force Feed Oiling Oil is fed to lubrication points by a pump.

Forced Air Air movement produced by a fan.

Forced Circulation Evaporator Evaporator with forced air passing across it.

Forced Convection Heat transfer by the movement of a liquid or vapor by a mechanical means such as a pump or fan.

Forced Draft Burner A burner in which combustion air is supplied by a blower.

Forced Draft Cooling Tower A cooling tower utilizing a fan to draw air through rather than natural draft.

Forced Draft Evaporator (see forced circulation evaporator)

Fossil Fuels Mineral fuels; mainly hydrocarbons, such as petroleum found within the top layer of the earth's crust.

Four-Way Valve Multi-ported valve used for reverse cycle heat pumps.

Fractionation Tendency for refrigerants contained in a zeotropic blend to vaporize and separate.

Free Area The total area of an opening in a grill or register through which air passes.

Free Wheeling Allowed to move or rotate without obstruction.

Freeze Drying Dehydration process that involves freezing the material first.

Freeze-up Frost or ice formation on an evaporator that restricts airflow or liquid flow through the evaporator.

Freezer Burn Damage to improperly packaged food product due to moisture being drawn out.

Freezing Change of state from liquid to solid.

Freezing Point The temperature at which a liquid will solidify upon removal of heat.

Freezing Point Depression The lowered freezing point of a liquid resulting from mixing in an additive.

Freon Trade name for a family of synthetic chemical refrigerants manufactured by DuPont, Inc.

Frequency The number of complete cycles in a unit of time.

Friction Force resisting the relative motion of two surfaces in contact, solid or liquid.

Friction Head In a hydronic system, the loss in pressure resulting from the flow of water in the piping system.

Front Seated A closed refrigeration valve is considered to be front seated.

Frost Back A condition in which liquid refrigerant boils in the suction line and produces a frosted surface on the line.

Frostbite Damage caused to skin and tissue due to extreme cold.

Frost Control, Automatic A control that automatically reverses a refrigeration system to remove frost/ice from the evaporator.

Frost Free Refrigerator A refrigerated cabinet that operates with an automatic defrost.

Frost Line The depth to which the ground freezes over a winter season. The frost line is usually set at 12 in below the deepest recorded frost penetration.

Frozen When a liquid has turned to a solid.

Fuel Oil Liquid petroleum fossil fuel used for an oil fired furnace.

Full Load Amperage (FLA) The amount of amperage an inductive load (motor) will draw at its full design load.

Furnace That part of a warm air heating system in which combustion takes place.

Fuse Electrical safety device consisting of a strip of fusible metal in a circuit that melts when the circuit is overloaded.

Fusible Link Link within an electrical circuit that will melt and open due to excessive temperature.

Fusible Plug A plug with a low melting temperature metal to release pressure in the event of a fire.

Gain Increase in the electronic amplification of a signal.

Galvanic Chemically generated current resulting from two dissimilar conductors immersed in an electrolyte.

Galvanic Action The destruction of one metal by electrolysis when two different metals are joined.

Gang Mechanical connection of two or more switches.

Gas Valve Valve used to control the flow of gas.

Gasket A resilient material used between mating surfaces to provide a leakproof seal.

Gas A substance in the vapor state.

Gas, Noncondensable A gas that will not form into a liquid under typical pressure-temperature conditions.

Gate Valve Valve with a vertical sliding gate normally fully open or fully closed, not throttled.

Gauge, Compound A pressure indicating instrument that measures pressures both above and below atmospheric pressure.

Gauge, Gas Manifold Pressure A direct reading gauge for measuring the gas manifold pressure.

Gauge, High Pressure An instrument used to measure pressures above atmospheric pressure in the 0–500 psig range.

Gauge, Low Pressure An instrument used to measure pressures above atmospheric up to 50 psig.

Gauge, Manifold A device that contains a combination of gauges and control valves to control the flow of refrigerant for service applications.

Gauge Port Access connection to attach gauges.

Gauge, Standard An instrument designed to measure pressures above atmospheric.

Gauge, Vacuum An instrument used to measure pressures below atmospheric.

Generator A machine that converts mechanical energy into electrical energy (also see Alternator).

Geothermal Heat that comes from within the earth.

Geothermal Heat Pump (see Ground Coupled Heat Pump)

Geothermal Well A drilled well in which the returned water is returned to the same well from which the supply water is taken.

Germanium Semiconductor material used for the manufacture of transistors.

Global Warming Increase in the average measured earth temperature.

Global Warming Potential (GWP) Relative scale used to determine the increase in global warming attributed to a piece of operating equipment.

Globe Valve Valve with a spherical disk and seat that may be used for throttling.

Glow Coil Automatically relights the pilot for a gas burner.

Glycol Antifreeze.

Grade Level The top surface of the earth.

Graduated Cylinder (see Charging Cylinder)

Grain Unit of weight measure. 7,000 grains equal 1lb.

Gram Metric unit of weight measure.

Gravity Flow (see Gravity System)

Gravity System A heating system in which the distribution of the warm air or water relies upon natural convective currents. There is no fan or pump.

Green Construction Practices used today that efficiently use energy, reduce waste and pollution, and create a healthy environment for the occupants.

Grill An ornamental or louvered opening through which air enters or leaves a duct system or area.

Grommet A round or oval shaped rubber, metal, or plastic shield to protect wire and pipe cabinet penetrations.

Gross Capacity, Heating The gross capacity of a heat pump in the heating mode is the total amount of heat energy transferred to the inside air. This is made up of the heat energy picked up from a heat source (air or liquid) plus the heat energy of the electrical power required to operate the heat pump.

Gross Output A rating applied to boilers. It is the total quantity of heat that the boiler will deliver and at the same time meet all limitations of applicable testing and rating codes.

Ground Connection between an electrical circuit and the earth.

Ground Coil, Earth Coil A heat exchanger coil buried in the earth that is used to either remove heat energy from the earth or add heat energy to the earth.

Ground Coupled Heat Pump A heat pump that uses a ground coil to exchange heat.

Ground Fault An electrical leak from the circuit to ground.

Ground Fault Circuit Interrupter (GFCI) Breaker specifically designed to open the circuit in the event of a ground fault.

Ground Wire An electrical wire that will safely conduct electricity from a structure into the ground.

Guide Vanes, Inlet, Prerotation Located at the inlet of centrifugal compressors and fans to vary capacity.

Gun Burner Oil forced through the burner orifice is atomized as it enters the furnace.

Halide Refrigerants Family of refrigerants containing halogen chemicals.

Halide Torch Type of torch used to detect halogen refrigerant leaks.

Halogens Compounds composed of fluorine, chlorine, bromine, iodine, and astatine.

Hand Truck Two wheeled dolly used for moving heavy objects.

Hanger Device used to support tubing, piping, ductwork, and so on.

Harvest Cycle Term used when ice is released from the freezing cells in an ice machine.

Head Pressure difference.

Head, Pressure Control A pressure operated control that opens an electrical circuit if the pressure exceeds the cutout point of the control.

Head, Static Pressure of a liquid or vapor in terms of the height of a column of water or mercury.

Head, Total In flowing fluid, the sum of the static and velocity pressures at the point of measurement.

Head, Velocity In flowing fluid, height of fluid equivalent to its velocity pressure.

Head Pressure The pressure in the condensing or high side of the refrigeration system.

Header A piping arrangement for interconnecting two or more supply or return taps of a boiler.

Heat A form of energy. Heat affects the molecular activity of a substance. This is reflected in the temperature of the substance. The addition of heat energy increases the molecular activity and temperature. The removal of heat energy lowers the molecular activity and temperature.

Heat Anticipator A resistor in a room thermostat that shuts the heating cycle off prematurely.

Heat Coil (see Heating Coil)

Heat Exchanger A device used to transfer heat energy from a higher temperature to a lower temperature. Evaporators, condensers, and earth coils are examples.

Heat Gain Total amount of heat absorbed by a building used to determine HVAC loads.

Heating Coil A heat transfer device designed to add heat to liquid or vapor.

Heating Control Device to control heating function.

Heating Mode The operating phase of a system that is adding heat energy to an occupied area.

Heating Seasonal Performance Factor (HSPF) The total heating output of a heat pump during its normal annual usage period for heating divided by the total electric power input in watt-hours during the same period.

Heating Value The number of Btu produced by the combustion of 1ft³ of gas.

Heat Lag When a substance is heated on one side, it takes time for the heat to travel through the substance.

Heat, Latent Heat energy used to change the state of a substance; solid to liquid and liquid to vapor by heat addition, or vapor to liquid and liquid to solid by heat removal, without a change in the temperature.

Heat Load The amount of heat energy, measured in Btu/hr, that is required to maintain a given temperature in a conditioned area at design conditions both inside and outside the conditioned area.

Heat Loss The rate of heat transfer from a heated building to the outdoors.

Heat Motor An electrical device that produces motion by means of the temperature change of bimetal elements. Used to produce time delay in the sequence of operation of a device (also see Sequencer).

Heat of Compression The heat added to the refrigerant by the work being done by the compressor.

Heat of Fusion The heat energy needed to accomplish the change in state of a material between a liquid and solid; addition for solid to liquid, removal for liquid to solid.

Heat Pipe Liquid filled pipes used in high efficiency gas furnaces.

Heat of Respiration When carbon dioxide and water are given off by foods in storage.

Heat Pump A name given to an air conditioning system that is capable of either heating or cooling an area on demand.

Heat Pump, Air-to-Air A device that transfers heat between two different air quantities in either direction on demand.

Heat Pump, Air-to-Liquid A device that transfers heat from an air source to a liquid by means of a refrigeration system.

Heat Pump, Liquid-to-Air A device that transfers heat between liquid and air in either direction on demand.

Heat Pump, Liquid-to-Liquid A device that transfers heat between two different liquids in either direction on demand.

Heat Pump, Water Heater An air-to-liquid refrigeration system used to heat domestic water with air as the heat source.

Heat Pump; Water Heater, Remove The refrigeration system is a complete unit designed to be connected to an existing water tank.

Heat Pump; Water Heater, Self Contained The component parts of the refrigeration system (condenser) are an integral part of the hot water tank.

Heat Reclaim Utilizing the heat rejected by the condenser for other heating purposes.

Heat Recovery System System utilizing an energy recovery ventilator.

Heat Recovery Ventilator (see Energy Recovery Ventilator)

Heat, Sensible The heat energy used to change the temperature of a material—solid, liquid, or vapor—without a change in state.

Heat Sink A place or material into which heat energy is placed. In a heat pump, the air outside the house is used as a heat sink during the cooling cycle.

Heat Source A place or material from which heat energy is obtained. In an air source heat pump, the air outside the house is used as a heat source during the heating cycle.

Heat, Total The sum of both the sensible and latent heat energy in air. Expressed as Btu/lb of air.

Heat Tape Electrical resistance heating wire that is wrapped around drain piping to prevent freezing.

Heat Transfer Movement of heat energy from one body or substance to another. Heat may be transferred by any combination of or all of the three methods radiation, conduction, and convection.

Heat Transfer Coefficient (U) Value assigned to designate heat transfer through a combination of given materials.

Heat Transfer Rate (Q) Amount of heat transferred per unit of time.

Helix Coil Bimetal coil used for dial thermometers.

Henry (H) The unit of inductance.

Hermetic Completely sealed.

Hermetic Motor Compressor drive motor sealed within the same casing that contains the compressor.

Hertz (Hz) Measure of frequency.

Hg Symbol for mercury.

High Glide Blend The range from the bubble point to the dew point is greater than 1°F at constant pressure.

High Efficiency Gas Furnace Furnace rated at 90% AFUE or better.

High Efficiency Particulate Air Filter (HEPA) Removes at least 99.97% of airborne particles 0.3 micrometers in diameter.

High Limit Control Safety that shuts off the furnace burner if the bonnet temperature is too high.

High Pressure Cutout An electrical pressure control switch operated by the high side pressure that is set to stop the compressor if the pressure safety limit is reached.

High Side Parts of a refrigerating system that are under condensing or discharge pressure.

High Side Float Refrigerant flow control located in the condenser.

High Temperature Refrigeration System with evaporator temperatures above 35°F.

High Vacuum Pump (see Deep Vacuum)

High Velocity System Usually large commercial or industrial air distribution systems designed to operate with static pressures of 6–9 in WC.

Horizontal Furnace The air flows horizontally through the furnace.

Horsepower A unit of power equal to 33,000 ft-lb of work per minute.

Hot Gas Compressor discharge vapor.

Hot Gas Bypass Method of compressor capacity control.

Hot Gas Defrost A defrosting system in which hot refrigerant gas from the compressor is directed through the evaporator to remove frost or ice from the evaporator.

Hot Gas Line The refrigerant tube that carries the high pressure, high temperature refrigerant vapor from the compressor to the condenser.

Hot Junction That part of a thermoelectric circuit that releases heat.

Hot Pulldown Lowering the temperature of a warm space.

Hot Surface Ignition A silicon carbide element is heated for the purpose of lighting the main burner.

Hot Water Heating System System that distributes hot water with pumps for heating a building.

- Hot Wire** Live wire with voltage potential to ground.
- Humidifiers** Device that directs water spray or mist into an airstream for humidification.
- Humidistat** A control that is affected by changes in the relative humidity in air. It is often used to control the operation of a humidifier.
- Humidity** Related to the amount of water vapor in the air.
- Hunting** Cycling above and below a setpoint such as a valve continuously opening and closing.
- Hydraulics** The use of fluid properties for the purpose of fluid power.
- Hydrocarbon** Any of a number of compounds composed of carbon and hydrogen.
- Hydrochlorofluorocarbon (HCFC)** Refrigerant composed of hydrogen, chlorine, fluorine, and carbon.
- Hydrofluorocarbon (HFC)** Refrigerant composed of hydrogen, fluorine, and carbon.
- Hydrogen** A colorless, odorless, highly flammable gas. It is the lightest of all elements.
- Hydrofluoro Olefins (HFO)** Newly developed types of refrigerant that have a low global warming potential.
- Hydrometer** Floating instrument used to measure specific gravity of a liquid.
- Hydronics** Pertaining to heating or cooling with water.
- Hygrometer** An instrument used to measure the percentage of moisture (relative humidity) in air.
- Hygroscopic** Ability of a substance to absorb and retain moisture.
- Ice Bank** A thermal accumulator in which ice is formed or charged during off peak periods of refrigeration demand, and used during peak demand for refrigeration to supplement the compressor capacity by melting the ice.
- Ice Bin** Location where ice is collected and stored for later use by an ice machine.
- Ice Harvest Switch** A device located at the end of the water plate. It resets the timer on the status indicator control card after each ice harvest.
- Ice Maker** A cyclic-type automatic ice making machine that has separate and sequential water fill, freezing, and ice harvesting phases for the production of ice.
- Ice Ring** An accumulation of ice at the bottom of the outdoor coil due to incomplete defrost operation.
- Identification Plate** Equipment data or name plate.
- Idler** A pulley used on some belt drives to provide the proper belt tension.
- Ignition System** Method of lighting a furnace.
- Ignition Temperature** The minimum temperature at which combustion can be started.
- Ignition Transformer** A transformer designed to provide a high voltage current for furnace electrodes.
- Impedance** A type of electrical resistance that is only present in alternating current circuits.
- Impeller** Rotating part of a centrifugal pump.
- Impingement** (see Flame Impingement)
- Incandescent** Heat driven light emissions allowing an object to glow from the heat.
- Inches Hg Pressure** Measurement of pressure in inches of mercury (in Hg) absolute.
- Inches Hg Vacuum** Measurement of vacuum in inches of mercury (in Hg) vacuum.
- Inclined Water Manometer** (see Manometer, Inclined)
- Incomplete Combustion** A condition where a portion of the fuel passing through a furnace remains unburned.
- Indoor Air Quality** A measurement of the factors attributing to the air quality condition within a building.
- Indoor Coil** The portion of a heat pump that is located in the house and functions as the heat transfer point for warming or cooling indoor air.
- Induced Draft Burner** A burner that depends on draft induced by a fan or blower at the flue outlet to draw in combustion air and vent flue gases.
- Induced Magnetism** Ability of a magnetic field to induce magnetism in a metal.
- Inductance** The characteristic of an alternating current circuit to oppose a change in current flow.
- Induction** The act that produces induced voltage in an object by exposure to a magnetic field.
- Induction Motor** An AC motor that operates on the principle of the rotating magnetic field. The rotor has no electrical connection, but receives electrical energy by transformer action from field windings.
- Inductive Circuit** Electrical circuit where the current lags the voltage.
- Inductive Load** A device that uses electrical energy to produce motion.
- Inductive Reactance** Opposition, measured in ohms, to an alternating or pulsating current.
- Inerts** Noncombustible substances in a fuel, or in flue gases, such as nitrogen or carbon dioxide.
- Infiltration** The air that leaks into the refrigerated or air conditioned space.
- Infrared** Unnoticeable rays just below red in the visible spectrum that transfer heat by radiation.
- Infrared Humidifier** A humidifier that utilizes infrared lamps to evaporate the water into the airstream.
- Infrared Lamp** An electrical device that emits infrared rays.
- Inherent Motor Protection** Built in motor protection such as a thermal overload located in the winding.
- Inhibitor** Substance that prevents a chemical reaction.
- Injection** Term used for a hydronic system circulating pump forcing water into a secondary heating loop.
- In Phase** The condition existing when two waves of the same frequency have their maximum and minimum values of like polarity at the same instant.
- Input/Output Board** Circuit board with measured inputs and controlled outputs.
- Inspection** To examine equipment and installation and compare to established guidelines and codes.
- Instrument** The addition of sensors with feedback and control loops to an existing system.
- Insulation, Electric** A substance that is a poor conductor of electricity with few free electrons.
- Insulation, Thermal** Substance used to retard or slow the flow of heat through a wall or partition.
- Insulator** Nonconductive material such as glass, rubber, or plastic used to shield bare wires and electrical connections.
- Integrated Circuit** A miniaturized electronic circuit consisting of mainly semiconductor devices.
- Integrated Circuit Board** Electronic circuits are manufactured on a thin surface of semiconductor material that is also referred to as microchip or just chip.

Interlock A safety device that allows power to a circuit only after a predetermined function has taken place.

Intermittent Absorption Cycle Closed system charged with ammonia and water and activated by a gas burner.

Intermittent Ignition Furnace ignition system that operates only as required.

Internal Motor Overload (see Inherent Motor Protection)

International Green Construction Code (IGCC) Comprehensive set of requirements intended to reduce the negative impact of buildings on the natural environment.

Interstate Commerce Commission (ICC) Federal regulatory body to oversee common carriers such as railroads and trucking.

Inverter An electrical device for converting DC to AC.

Ion An ion is an atom that is either negatively (anion) or positively (cation) charged.

Ion Generator A device that charges particles.

IR Drop Voltage drop resulting from current flow through a resistor.

Isolation Relays A relay designed to prevent undesirable electrical feedback.

Isothermal At constant temperature.

Joints, Brazed A solder type connection or joint obtained by the joining of the metal parts with metallic mixtures or alloys that have a melting temperature above 1,000°F and up to 1,500°F.

Joint, Soldered A solder type connection or joint obtained by the joining of the metal parts with metallic mixtures or alloys that have a melting temperature below 1,000°F.

Joint, Welded A solder type pipe connection or joint obtained by the joining of the metal parts with metallic mixtures or alloys that have a melting temperature above 1,500°F.

Joule A measure of heat in the metric system.

Joule-Thomson Effect A drop in gas temperature due to a sudden increase in its volume.

Journal, Crankshaft Part of the shaft that contacts the bearing.

Junction Box Group of electrical terminals housed in protective box or container.

Kelvin Scale (K) Thermometer scale on which the unit of measurement equals the centigrade degree and according to which absolute zero is 0°K, the equivalent of -273.16°C.

Kilocalorie (C) Measure of heat equal to 1,000 calories.

Kilometer (km) Measure of distance equal to 1,000 m.

Kilopascal (kPa) A measure of pressure in the metric system.

Kilovoltampere (kVA) Measure of electrical work equal to 1,000 voltamperes.

Kilowatt (kW) A unit of electrical energy equal to 1,000 W.

Kilowatt Hour (kWh) A unit for measuring electrical energy equal to 3,413 Btu.

Kinetic Energy Energy in motion.

King Valve The valve located at the outlet of the receiver.

Lacquer Clear coating on wire that provides insulation for electric windings.

Ladder Diagram Electrical diagram that shows a circuit by circuit arrangement. The power lines are the "rails"

of the ladder, and each individual circuit is a "rung" of the ladder.

Lagging Thermal insulation around pipes and boiler jackets.

Latent Heat Heat change that occurs when a substance changes state.

Latent Heat of Condensation Heat released when a gas condenses to a liquid.

Latent Heat of Deposition Heat released when a gas freezes to a solid.

Latent Heat of Fusion Heat released to change a liquid to a solid.

Latent Heat of Sublimation Heat absorbed when a solid changes directly to a gas without first becoming a liquid.

Latent Heat of Vaporization Heat absorbed when a liquid changes to a vapor.

Leadership in Energy and Environmental Design (LEED) Green Construction rating system created by the U.S. Green Building Council.

Leads, Meter The wires that are used to connect an electric meter to the circuit being tested.

Leads, Motor The connection wires on a motor.

Leak Detector A device or instrument used to detect and locate leaks of gases or vapors.

Light Emitting Diode (LED) A diode that lights up when electrical current flows through it.

Legionella The bacteria that can thrive in cooling towers and cause Legionnaire's disease.

Legionnaire's Disease A bacterial pneumonia named after an outbreak at the July 1976 American Legion convention in Philadelphia.

Limit Control A device used to open or close electrical circuits if temperature or pressure reaches preset limits.

Limit Switch A normally closed switch on a furnace that opens if the furnace temperature exceeds the limit setpoint.

Line Diagram Another name for a ladder or schematic diagram.

Line Set Copper tubing used for the liquid and vapor lines to connect the two parts of split system air conditioners and heat pumps.

Line Tap Valve (see Piercing Valve).

Line Voltage Voltage existing at wall outlets or terminals of a power line system above 30 V.

Line Voltage Thermostat Thermostat designed for use with voltages of 120 V or higher.

Liquefied Natural Gas (LNG) Natural gas that has been cooled until it becomes a liquid.

Liquefied Petroleum Gases (LP, LPG) Fuel that is stored as a liquid under pressure, but used as a gas. Includes any fuel gas that is composed predominantly of any of the following hydrocarbons: propane, propylene, normal butane or isobutene, and butylenes.

Liquid A fluid form of matter that takes on the shape of its container but whose volume is not determined by the volume of the container.

Liquid Charge Bulb A temperature sensing bulb with enough refrigerant to ensure that there is always some quantity of liquid in the bulb.

Liquid Floodback Liquid refrigerant returning to the suction side of a compressor during operation.

Liquid Hammer A pounding sound made by the sudden increase in static pressure in the pipes when flowing liquid is stopped suddenly by the closing of a valve.

Liquid Injection Cooling low temperature compressors by introducing small amounts of liquid refrigerant into the shell of the compressor.

Liquid Line The tube that carries liquid refrigerant from the condenser or liquid receiver to the pressure reducing device.

Liquid Nitrogen (LN₂) Nitrogen in liquid form.

Liquid Receiver Cylinder connected to condenser outlet for storage of liquid refrigerant in a system.

Liquid Refrigerant Charging Adding refrigerant to a refrigeration system in liquid form.

Liquid Refrigerant Recovery Removing refrigerant from a system in liquid form.

Liquid Slugging Hydraulic pressures created by liquid that is trapped in the clearance pocket of a reciprocating compressor during operation.

Liquid-Vapor Valve The valve on refillable refrigerant cylinders that allows either liquid or vapor to be removed from the cylinder.

Liter (L) Metric unit of volume.

Lithium Bromide The absorbent in large absorption chillers that use water as the refrigerant.

Load The amount of heat per hour that the refrigeration system is required to supply at design conditions. The amount of electrical energy expected to be connected to an electrical power supply.

Load Matching Matching the system capacity to the heat load.

Load Shedding Removing electrical loads in a building for periods of time as part of an energy management strategy.

Locked Rotor Amperage (LRA) The amount of energy a motor will draw under stalled conditions.

Lock Out Relay A control scheme that prevents the restarting of a compressor after a safety control opens, even after the safety control resets itself.

Louvers Sloping, overlapping boards or metal plates intended to permit ventilation and shed falling water.

Low Ambient Control A device used to allow proper condensing operation at low outdoor ambient temperatures.

Lowboy Furnace A furnace with the blower and heat exchanger side by side having both the return and supply air connections at the top of the furnace.

Low Glide Blend A zeotropic refrigerant with a typical temperature difference between the bubble point and the dew point of less than 3°F.

Low-Loss Fitting A fitting on the end of a refrigerant hose designed to prevent refrigerant from leaving the hose when it is disconnected from the system.

Low Pressure Control A device used to start or stop the system operation when the low pressure (low side pressure, suction pressure) drops to preset limits.

Low Pressure Cutout Device used to keep the low side evaporating pressure from dropping below a certain pressure.

Low Side The portion of the refrigeration system that operates at the evaporator pressure. Consists of the pressure reducing device, evaporator, and suction line.

Low Side Float Controls flow into the evaporator using a mechanical float located on the low side of the system.

Low Side Pressure Pressure in the low side of the refrigeration system. Also called low side pressure or suction pressure.

Low-Temperature Refrigeration a commercial refrigeration system with an evaporator saturation temperature between -30°F and 10°F and a nominal compressor rating point of -10°F.

Low Voltage An AC voltage system no higher than 30 V with a maximum rating of 100 VA. Typically 24 V in air conditioning control systems.

Low Voltage Control Controls designed to operate at voltages of 20–30 V.

Low-Voltage Thermostat A thermostat designed for a low voltage control system.

MBH Abbreviation for 1,000 Btu/hr.

Machine Room A room in a building dedicated to mechanical equipment.

Machine Screw Fastener with a head, a cylindrical body, and fine threads.

McLeod Gauge An instrument for accurate measurement of very low pressures.

Magnetic Clutch Assembly that transfers power from an outer pulley to an open compressor when energized.

Magnetic Field The space in which a magnetic force exists.

Magnetic Flux The lines of force around a magnetic field.

Magnetic Gasket A door seal on a refrigerator or freezer that uses a magnet to ensure tight closure.

Magnetic Overload Protection Breaks the circuit to an electric motor when high current draw produces a strong magnetic field.

Magnetism A force that attracts certain metals like iron and alloys of nickel and cobalt

Makeup Air Fresh air. The air supplied to a building to replace air exhausted from the building.

Makeup Water Line The line connected to the loop system for filling or adding liquid as necessary.

Male Thread A pipe or fitting with a thread on the outside.

Manifold A pipe with several outlets for distributing fluid flow.

Manifold Gauge A device constructed to hold compound and high pressure gauges and valves to control flow of fluids through it.

Manometer An instrument used to measure the pressure of gases or vapors. The gas pressure is balanced against a column of liquid, such as water or mercury, in a U-shaped tube open to atmospheric pressure.

Manometer, Inclined A manometer on which the liquid tube is inclined from horizontal to produce wider, more accurate readings over a smaller range of readings.

Manual Reset A safety device with a button or flag that must be pushed in order to restore normal operation.

Mapp Gas Dow Chemical trade name for methylacetylene-propadiene, a liquefied petroleum gas that burns hotter than propane and is sometimes used for soldering and brazing.

Marine Water Box The water manifold portion of a chiller or boiler with a removable cover.

Mass A quantity of matter cohering together to make one body.

Matched Belts A set of belts that are precisely sized to the same circumference for use on a multiple belt drive.

Matched System A split system air conditioner or heat pump whose indoor and outdoor components are designed for use with each other.

Matter The substance that physical objects are made of. Matter has weight and takes up space.

Maximum Operating Pressure (MOP) The maximum pressure a pressure limiting thermostatic expansion valve will allow in the evaporator.

Mean Annual Earth Temperature The mean average temperature of the earth as it changes throughout the year. The largest factor for earth temperature change is sunshine.

Mean Temperature Difference The average temperature between the temperature before a process begins and the temperature after the process is completed.

Mechanical Controls Controls that operate by purely mechanical means, such as pressure regulating valves.

Mechanical Cycle Cycle that is a repetitive series of mechanical events.

Medium-Temperature Refrigeration A commercial refrigeration system with a saturated evaporator temperature between -10°F and 30°F and a nominal compressor rating point of 20°F .

Mega (M) SI prefix for 1,000,000.

Megohm (M Ω) 1,000,000 Ω of electrical resistance.

Megohmmeter A meter that can read millions of ohms of resistance.

Melting Point Temperature at atmospheric pressure, at which a substance will melt.

Mercaptan An odorant additive that gives natural gas its characteristic odor.

Mercury Bulb An electrical circuit switch that uses a small quantity of mercury in a sealed glass tube to make or break electrical contact with terminals within the tube.

Meter Metric unit of linear measurement.

Metering Device Controls the flow of refrigerant into the evaporator of a refrigeration system.

Methane A hydrocarbon gas with the formula CH_4 , the principal component of natural gas.

Metric System The measurement system used worldwide based on units of ten.

Micro A combining form denoting one millionth.

Microfarad (MFD) The unit of measurement for capacitance, equal to a millionth of a farad.

Micrometer A device for making measurements accurate to 1/1,000th of an inch.

Micron (μm) A metric unit of length equal to one millionth (1/1,000,000) of a meter used for measuring vacuums.

Micron Gauge Measures deep vacuums in microns of mercury absolute pressure.

Microprocessor A single integrated chip that combines all the functions of a computer central processing unit.

Midposition Description of the position of a refrigeration service valve when it is in between the front seat and back seat of the valve.

Migration of Refrigerant Refrigerant moving from one part of a refrigeration system to another during the off cycle.

Milli (m) A term used to denote one thousandth (1/1,000) of a unit. For example, a milliampere is 1/1,000 of an ampere.

Mineral Oil (MO) Lubricant made by refining crude oil. It is used in CFC and HCFC systems.

Minimum Efficiency Reporting Value (MERV) System used to compare the relative efficiency of air filters.

Miscibility The ability of a refrigerant and a lubricant to mix.

Modulating A type of device or control that tends to adjust by increments (minute changes) rather than by either full on or full off operation.

Module A group of components or circuits in a single housing. Usually electronic.

Moisture Indicator Instrument used to measure the moisture content of a refrigerant.

Mold A fungus that thrives in wet environments and can contribute to indoor air quality problems.

Molecular Motion Vibration and movement of individual molecules of a substance that increases as the level of molecular energy increases.

Molecule The smallest portion of a compound that retains the identity and characteristics of the compound.

Mollier Diagram Graph of refrigerant pressure, heat, and temperature properties.

Montreal Protocol An international agreement to control the production and release of ozone depleting substances.

Motor Converts electrical energy into rotating mechanical motion using electromagnetism.

Motor, Permanent Split Capacitor A single phase induction motor that uses both run and start windings in the running mode. The start winding is connected in series with a capacitor to change the electrical characteristics of the winding.

Motor Burnout A condition in a motor where the insulation has deteriorated due to overheating.

Motor Control A control to start and stop a motor at preset pressures or temperatures.

Motor Starter A high capacity electrical contact operated by an electromagnetic coil and containing properly sized overload cutouts.

Muffler A refrigeration component located immediately after the compressor that reduces sound and vibration set up by the pulsing flow of refrigerant.

Mullion Stationary structure between two doors in a refrigerator or freezer.

Mullion Heater A heater that keeps the mullion temperature above the dew point.

Multimeter A meter that reads multiple electrical properties, typically including volts and ohms.

Multiple Circuit Coil A coil that has more than one path for simultaneous fluid flow.

Multiple Evacuation Evacuating a system, charging it with dry nitrogen, releasing the nitrogen, and then evacuating the system again.

Multistage System A system that delivers heating or cooling in two or more steps, or stages.

Naphthenic Oil Mineral oil that has a low wax content.

National Electrical Code (NEC) A code of electrical rules based on fire underwriters' requirements for interior electric wiring.

National Environmental Balancing Bureau (NEBB) An organization that certifies companies and technicians in building science services, including building commissioning, testing, adjusting, and balancing, and clean rooms.

National Fuel Gas Code (NFPA 54) A safety code for the installation and utilization of fuel gas piping systems and equipment.

National Fire Protection Association (NFPA) Organization dedicated to fire prevention that writes the National Electric Code and the National Fuel Gas Code.

National Green Building Standard Developed by the National Association of Home Builders that identifies green building practices in six different categories.

National Institute of Standards and Technology (NIST) A nonregulatory federal agency within the U.S. Department of Commerce that sets standards for measurement and technology.

National Pipe Taper (NPT) The standard specification for pipe threads.

Natural Convection Circulation of a gas or liquid due to difference in density resulting from temperature differences.

Natural Draft Airflow created by natural convection.

Natural Draft Cooling Tower A cooling tower that depends on natural convection instead of a fan.

Natural Gas Any gas found in the earth, as opposed to gases that are manufactured.

Needle Valve A valve used to accurately control very low flow rates of fluids.

Negative Electrical Charge An electrical charge resulting from an atom or object having more electrons than protons.

Negative Temperature Coefficient Thermistor (NTC) A semiconductor whose electrical resistance increases as its temperature decreases. Commonly used to measure temperature of outdoor coils on heat pumps to initiate and terminate defrost cycles.

Neoprene A synthetic rubber that is resistant to hydrocarbon oil and gas.

Net Oil Pressure The difference between the pressure at the outlet of the oil pump and the crankcase pressure in a compressor.

Net Refrigeration A measure of the amount of cooling that takes place in an evaporator. It is the enthalpy of the gas leaving the evaporator minus enthalpy of the gas entering the evaporator. The units are Btu/lb.

Net Stack Temperature The difference between the temperature of the flue gases and the temperature of the combustion air.

Neutralizer A chemical added to a system to counteract the effect of acids.

Neutron A subatomic particle located in the nucleus of an atom that does not have an electrical charge.

Newton (N) A measure of force in the SI system. One Newton accelerates one kilogram one meter per second squared.

Nichrome An alloy of nickel and chromium used in the construction of electrical heating elements.

Nitrogen A common, inert gas. The air is approximately 78% nitrogen.

No-Frost Freezer A freezer with an automatic defrost cycle.

Noise Dosimeter An instrument used to measure exposure to sound levels.

Nominal The named rating, or standard rating, for quantities and dimensions whose actual value is variable.

Nominal Size Measurement for tubing and pipe equal to the approximate inside diameter.

Nominal Voltage The name plate voltage for an appliance. AHRI standard 110–2002 sets the nominal voltages for air conditioning equipment.

Noncondensable Gas Gas that does not change into a liquid at operating temperatures and pressures.

Nonferrous Group of metals and metal alloys that contain no iron; also metals other than iron or steel. In heating systems, the principal nonferrous metals are copper and aluminum.

Non-Frosting Evaporator A commercial refrigeration evaporator that operates above freezing.

Noninductive Load An electrical load that does not have any electromagnetic components.

Normally Closed (NC) Switch contacts closed with the circuit deenergized.

Normally Open (NO) Switch contacts open with the circuit deenergized.

North Pole The pole on a magnet that the magnetic lines of force flow out of.

Nozzle The device on the end of the oil fuel pipe used to form the oil into fine droplets by forcing the oil through a small hole to cause the oil to break up.

NOx A term for various compounds of nitrogen and oxygen that are byproducts of combustion.

Nut Driver A tool with a handle, shaft, and socket on the end for tightening and loosening hexagonal nuts and screws.

Odorant A substance added to an otherwise odorless, colorless, and tasteless gas to give warning of gas leakage and to aid in leak detection.

Off-Cycle Defrost A naturally occurring defrost in commercial refrigeration equipment with an evaporator temperature below freezing and a box temperature above freezing.

Off Mode Cycle That part of the operating mode when the system has been shut down by the controls.

Offset The difference between the control setpoint and the actual maintained condition.

Ohm (Ω) A unit of resistance.

Ohmmeter A meter for measuring electrical resistance.

Ohm's Law States the relationship between voltage, current, and resistance in a purely resistive circuit.

Oil Binding Physical condition when an oil layer on top of refrigerant liquid hinders it from evaporating at its normal pressure-temperature condition.

Oil Burner The part of an oil furnace or boiler that produces heat by burning fuel oil.

Oil Level Regulator Controls the level of oil in a compressor in a multiple compressor system.

Oil Pressure, Compressor The pressure created by the oil pump of a compressor with a positive pressure lubrication system.

Oil Pressure, Oil Burner The pressure created by the oil pump in an oil burner.

Oil Pressure Safety Switch A timed pressure differential switch that opens the control circuit to a compressor if the oil pressure drops below safe levels.

Oil Reservoir The vessel that holds reserve oil in an oil level control system used for a system with multiple compressors.

Oil Rings Expanding rings mounted in grooves and piston; designed to prevent oil from moving into compression chamber.

Oil Separator A device used to separate refrigerant oil from refrigerant gas and return the oil to crankcase of compressor.

Oil Slugging Hydraulic pressures created by oil that is trapped in the clearance pocket of a reciprocating compressor during operation.

One Pipe Fitting A specially designed tee for use in a one-pipe system to connect the supply or return branch into a circuit.

One Pipe System A forced hot water system using one continuous pipe or main from the boiler supply to the boiler return.

One Time Relief Valve A pressure relief device that must be replaced after it has opened.

One Time Fuse A fuse with little time delay in opening and little tolerance for surge current.

Open Circuit An interrupted electrical circuit that prevents electrical flow.

Open Compressor One with a separate motor or drive.

Open Display Case A commercial refrigerator or freezer that is designed to remain open on the top or front.

Open-Loop, Control System A control system where the controller output does not affect the condition the controller is sensing.

Open-Loop, Water System A recirculating water system that is open to the atmosphere somewhere in the system.

Open-Loop, Heat Pump A water source heat pump that uses groundwater for its water source.

Open Refrigeration System A refrigeration system that uses an open compressor.

Open Winding A motor winding with a break in it.

Operating Control Cycles system components during normal operation. Commonly used to refer to the control that cycles the compressor in a refrigeration system.

Operating Pressures The low and high side pressures in an operating refrigeration system.

Orifice An accurately sized opening that controls the flow of vapor or liquid at given pressures across the opening.

Orifice, Oil Metering A small hole in the pickup tube in the accumulator used to ensure oil return to the compressor in small easily handled quantities.

Orifice Spud A removable plug containing an orifice that determines the quantity of gas that will flow.

O-Ring An elastic seal shaped in a circle used for sealing mechanical parts.

Oscilloscope A fluorescent coated tube that visually shows an electrical wave.

Outdoor Coil The portion of a heat pump that is located outside the home and functions as a heat transfer point for collecting heat from or dispelling heat to the outside air.

Outside Air Atmosphere exterior to the conditioned area.

Overload Load greater than the load for which the system or mechanism was intended.

Overload Protector A device that will stop operation of the unit if dangerous conditions arise.

Oxidation A chemical reaction between oxygen and other materials that forms new compounds. Rust is iron oxidation.

Oxygen An element normally found in gas form that makes up approximately 21% of the atmosphere. It is required for combustion.

Ozone A gaseous form of oxygen (O₃).

Ozone Depletion Reduction of the ozone concentration in the stratosphere.

Ozone Depletion Potential (ODP) A rating of a chemical's potential to deplete stratospheric ozone. By definition, the ozone depletion potential of CFC 11 is 1.

Package Boiler A boiler having all components assembled as a unit.

Packaged Terminal Air Conditioner (PTAC) A small capacity, through the wall packaged air conditioner designed for use in motels, dorm rooms, and efficiencies.

Packaged Unit A complete refrigeration or air conditioning system in which all the components are factory assembled into a single unit.

Packing The material that is packed around the stem of a manual valve to seal it.

Paraffinic Oil Mineral oil with a high wax content.

Parallel Circuit connected so current has two or more paths to follow.

Parallel Circuit An electrical circuit in which there is more than one different path across the power supply.

Partial Pressures Condition where two or more gases occupy a space and each one creates part of the total pressure.

Parts per Million (ppm) A measurement of the concentration of gases and contaminants at relatively low levels.

Part Winding Start Starting a dual voltage, three phase motor using only half of the motor windings when used on low voltage to reduce the motor inrush current.

Pascal (Pa) The SI measurement of pressure equal to 1 N of force applied over a square meter of area.

Pascal's Law A pressure imposed upon a fluid is transmitted equally in all directions.

Passive Refrigerant Recovery Device A refrigerant recovery device that has no operating components.

Passive Solar Heating Solar heating that depends on architectural design rather than mechanical and electrical components.

Peltier Effect The principle that makes thermoelectric refrigeration work. When current flows through a thermocouple, one end heats up and the other cools down.

Permeance The ratio of water vapor flow to the vapor pressure difference.

pH A term based on the hydrogen ion concentration in water, which denotes whether the water is acid, alkaline, or neutral.

Permanent Magnet A magnet that retains in magnetic effect and produces its own magnetic field.

Permanent Split Capacitor Motor (PSC) (see Motor, Permanent Split Capacitor).

Phase, Electrical The number of separate sine wave forms providing power to an alternating current device.

Phase, Physics The physical state of a substance: solid, liquid, gas, or plasma.

Phase Change A substance changing from one physical state to another.

Phase Loss Monitor A safety device that monitors three phase current and shuts down a system or component if one of the three phases drops out.

Phase Reversal A rearranging of the three power legs in a three phase circuit that results in three phase motors reversing their rotation.

Photoelectricity A physical action wherein an electrical flow is generated by light waves.

- Photovoltaic Cell** A semiconductor device that converts sunlight into electricity.
- Pictorial Wiring Diagram** Shows the electrical components as they appear on the equipment and shows the actual routing and color of all interconnecting wiring.
- Piercing valve** A valve that bolts or brazes onto the outside of a pipe and pierces it to gain access to the system.
- Piezoelectric** A property of some crystals that produces electric potential when they are struck.
- Pilot** A small flame that is used to ignite the gas at the main burner.
- Pilot Duty Relay** A relay used for switching other controls. Only rated for switching small amounts of current.
- Pilot Generator** A device used to generate voltage in a millivolt heating system.
- Pilot Safety Valve** A valve that will shut off the main gas if the pilot flame is not proved.
- Pilot Switch** A control used in conjunction with gas burners. Its function is to prevent operation of the burner in the event of pilot failure.
- Pinch Off Tool** Device used to press the walls of tubing together until fluid flow ceases.
- Pipe** Used to convey fluids. Pipe is measured by its approximate inside diameter and has relatively thick walls compared with tubing.
- Piston** Close fitting part that moves up and down in a cylinder.
- Piston Displacement** Volume obtained by multiplying area of cylinder bore by length of piston stroke.
- Pitch** Pipe slope.
- Pitot Tube** A device that senses static and total pressure.
- Plenum** A cube shaped duct or box on the supply or return side of an air handling unit to connect the supply or return duct system to the unit.
- Pneumatic Controls** Controls that are operated by air pressure.
- Point of Vaporization** The location of the position in the evaporator coils where the last bit of liquid refrigerant is vaporized.
- Polarity** The condition denoting the direction of current flow.
- Pollen Count** An index that shows the number of pollen grains in a cubic meter of air.
- Polyalkylene Glycol (PAG)** A synthetic lubricant used with HFC refrigerants.
- Polybutylene (PB)** A plastic used for pipe material that has excellent creep resistance as well as high resistance to stress cracking. Recommended for earth loops.
- Polychlorinated Biphenyl (PCB)** A dielectric oil that was used in transformers and capacitors. It is no longer used because it is a carcinogen.
- Polyethylene (PE)** A plastic used for tubing for ground loop systems, cold water lines, and heat pump piping.
- Polyethylene, Cross Linked (PEX)** A derivative of polyethylene that is stronger, more elastic, and can withstand higher temperatures.
- Polyol Ester (POE)** A synthetic lubricant that can be used with most CFC, HCFC, and HFC based refrigerants.
- Polyphase** An electrical device or system that is designed to operate on more than one phase of alternating current.
- Polyphase Motor** An electric motor that is designed to operate on more than one phase of alternating current.
- Polystyrene** Plastic used as an insulation in some refrigerator cabinet structures.
- Polyvinyl Chloride (PVC)** A thermoplastic material used for making cold water piping and drain lines.
- Ponded Roof** Flat roof designed to hold a quantity of water.
- Positive Displacement** A compressor that compresses gas by filling the space occupied by the gas with a physical part, such as a piston.
- Positive Electrical Charge** An electrical charge resulting from an atom or object having more protons than electrons.
- Positive Pressure** A pressure above atmospheric pressure.
- Positive Temperature Coefficient Thermistor (PTC)** A semiconductor whose electrical resistance increases as its temperature increases. Sometimes used as an electronic start relay in the start circuits for compressors.
- Potable Water** Water that is suitable for human consumption.
- Potential** The amount of voltage or electrical pressure between two points of an electrical circuit.
- Potential Energy** Stored energy.
- Potential Relay** A relay that senses the back emf of the start winding and drops out the starting components of a compressor.
- Potentiometer** A variable resistor.
- Pounds per Square Inch (psi)** Unit of pressure measurement.
- Pounds per Square Inch Absolute (psia)** Pressure measured in pounds per square inch absolute.
- Pounds per Square Inch Gauge (psig)** A symbol or initials used to indicate pressure in pounds per square inch gauge.
- Pour Point** Lowest temperature at which a particular oil will pour.
- Powder Actuated Tool (PAT)** A tool that drives nails and anchors into concrete and steel using gunpowder.
- Power** Time rate at which work is done or energy consumed. Source or means of supplying energy.
- Power Burner** A burner that uses a blower to force in combustion air and control the mixture of fuel and air.
- Power Element** Sensitive element of a temperature operated control.
- Power Factor** The rate of actual power as measured by a wattmeter in an alternating circuit to the apparent power determined by multiplying amperes by volts.
- Predictive Maintenance** Performing calibrated tests on operating equipment and comparing them to base line measurements so that equipment can be repaired or replaced as it wears, before it actually fails.
- Pressure** Force per unit area.
- Pressure, Absolute (psia)** (see Absolute Pressure)
- Pressure, Atmospheric** Pressure exerted by the atmosphere.
- Pressure, Back** The pressure the pump must overcome to be able to force the liquid into the pressure tank. The pressure in the tank.
- Pressure, Gauge (psig)** Pressure measured above atmospheric pressure.
- Pressure, Static (P_s)** The pressure in the system when the pump is idle.

Pressure, Suction The pressure in the low pressure or evaporator section of the refrigeration system.

Pressure Drop (ΔP) The pressure difference between two locations in a circuit, the difference being a result of flow resistance in the circuit.

Pressure-Enthalpy Diagram (PH) (see Mollier Diagram)

Pressure Gauge Instrument for measuring pressure in pounds per square inch gauge (psig).

Pressure Limiter Device that remains closed until a certain pressure is reached and then opens and releases fluid to another part of the system.

Pressure Motor Control A device which opens and closes on electrical circuit as pressures change to desired pressures.

Pressure Limiting Thermostatic Expansion Valve A thermostatic expansion valve that will not feed more refrigerant once it reaches its maximum operating pressure.

Pressure Operated Altitude Valve (POA) Device that maintains a constant low side pressure independent of altitude of operation.

Pressure Reducing Device The device used to reduce the pressure on the liquid refrigerant and thus the boiling point before entering the evaporator.

Pressure Reducing Valve A diaphragm operated valve installed in the makeup water line of a hot water heating system.

Pressure Regulator A device for controlling a uniform outlet gas pressure.

Pressure Relief Valve A device for protecting a tank from excessive pressure by opening at a predetermined pressure.

Pressure Switch An electrical switch that is opened and closed by changes in pressure.

Pressure-Temperature Chart (PT Chart) Shows refrigerant saturation pressures and temperatures.

Pressure-Temperature Plugs (P/T) Allow thermometers and pressure gauges entrance into a water system without draining or removing the pressure of the system.

Pressure-Temperature Relationship The predictable relationship between the pressure and temperature of a saturated mixture.

Pressure Transducer Produces a variable electrical signal based on the applied pressure.

Pressure Vessel An enclosure designed to hold pressure.

Pressure Water Valve A valve that controls the flow of water through a water cooled condenser based on the condenser pressure.

Preventative Maintenance Performing regularly scheduled maintenance in order to prevent equipment failure and shutdown.

Primary Air The combustion air introduced into a burner that mixes with the gas before it reaches the port.

Primary Control One type of operating controller for an oil burner.

Primary Voltage The voltage of the circuit supplying power to a transformer.

Primary Winding The input winding on a transformer.

Process Tube Length of tubing fastened to hermetic unit dome, used for servicing unit.

Product The material being cooled in a commercial refrigeration system.

Product Heat Load The heat that is added to the refrigeration system from the product being cooled.

Programmable Thermostat A thermostat that can be programmed to automatically change setpoints based on the time.

Propane A hydrocarbon fuel.

Propeller Fan A fan with blades mounted perpendicular to the shaft arranged in a circle. Airflow is parallel to the shaft.

Proportional Controller A control that can blend two streams of air or water in varying proportions.

Propylene Glycol A nontoxic chemical used for anti-freeze solutions in HVACR applications.

Proton A positively charged subatomic particle found in the nucleus of atoms.

Psychrometer An instrument used to measure the dry bulb and wet bulb temperatures of air.

Psychrometric Chart A chart that graphs the relationship of the temperature, pressure, and moisture content of air.

Psychrometrics The study of the thermodynamic and physical properties of air.

Puffback An explosion in the firebox of an oil burner accompanied by a puff of smoke created by delayed ignition. Potentially very hazardous.

Pulley A wheel with a groove around its circumference used for transmitting mechanical power using a belt designed to fit in the groove.

Pulse Combustion A series of small explosions that produces extremely efficient combustion.

Pulse Furnace A furnace that uses pulse combustion for high operating efficiency.

Pulse Width Modulation (PWM) A pulsing electronic signal that communicates based on the length of the pulses and the time intervals in between the pulses. Used in some types of electronic control systems.

Pump A motor driven device used to mechanically circulate water in the system.

Pump, Centrifugal A pump that works by taking water into the center of a high-rpm impeller and throwing it to the outside of the wheel using centrifugal force.

Pump, Screw Moves liquid using two intermeshing, auger shaped screws turning in opposite directions.

Pumpdown A service procedure where the refrigerant is pumped into the receiver.

Pump Head The difference in pressure on the supply and intake sides of the pump created by the operation of the pump.

Purging Releasing compressed gas to the atmosphere through some part or parts for the purpose of removing contaminants from that part or parts.

Pyrometer Instrument for measuring temperatures.

Quenching Submerging hot solid object in cooling fluid.

Quench Valve A valve used on transport refrigeration units to meter small amounts of liquid refrigerant into the suction side of the compressor to reduce the compressor discharge temperature.

Quick Connect Coupling A device that permits an easy and fast means of connecting two fluid lines or fittings together without the use of solder.

R Value, SI The thermal resistance of a building material in units of $K \cdot m^2/W$.

- R Value, U.S.** The thermal resistance of a building material in units of $\text{ft}^2 \cdot ^\circ\text{F} \cdot \text{h} / \text{Btu}$.
- Rack System** A commercial refrigeration system with multiple compressors manifolded together on a rack.
- Radiant Heating** A heating system in which only the heat radiated from panels is effective.
- Radiation** Transfer of heat by heat rays.
- Radiator** A heating unit exposed to view within the room or space to be heated.
- Radiator Valve** A valve installed on a terminal unit to manually control the flow of water through the unit.
- Radon** A naturally occurring radioactive gas sometimes found in basements and crawl spaces.
- Range** Pressure or temperature settings of a control.
- Rankine (R)** Absolute Fahrenheit scale.
- Rated-Load Amperage (RLA)** The current that a motor draws when it is operating at its rating condition.
- Reactance** Opposition to alternating current by either inductance or capacitance, or both.
- Reamer** A tool for removing the burr left by a tubing cutter.
- Receiver** A refrigeration component located after the condenser that stores high pressure liquid refrigerant.
- Receiver-drier** A refrigerant receiver that incorporates a desiccant bag for dehydrating the refrigerant.
- Reciprocal** The result of dividing any number into 1 is its reciprocal.
- Reciprocating** Action in which the motion is back and forth in a straight line.
- Reciprocating Compressor** A compressor that uses pistons, cylinders, and valves to compress gas.
- Recirculated Air** Return air passed through the conditioner before being again supplied to the conditioned space.
- Recirculated Water System** A heating or cooling system that reuses the same water by circulating the water through a closed loop.
- Reclaim** To reprocess refrigerant so that it meets the AHRI 700–2006 standard for new refrigerant.
- Recording Ammeter** An ammeter that can record the amp draw over a period of time either on paper or in the meter's memory.
- Recording Thermometer** A thermometer that can record the temperature over a period of time either on paper or in its memory.
- Recording Voltmeter** A voltmeter that can record voltage over a period of time either on paper or in the meter's memory.
- Recovery** Removing refrigerant from a system and storing it in an external container without cleaning or processing the refrigerant.
- Recovery Cylinder** A DOT approved cylinder for storing recovered refrigerant.
- Rectifier, Electric** An electrical device for converting AC into DC.
- Rectifier, Refrigeration** A component in an absorption system that condenses water vapor and returns it to the generator to improve ammonia concentration to the condenser.
- Recuperative Heat Exchanger** A secondary heat exchanger on high efficiency gas and oil furnaces that recovers heat from the combustion gases through condensation.
- Recycling** Removing refrigerant from a system, processing it using filters and oil separators, and storing it in an external container.
- Reducing Fitting** A pipe fitting designed to change from one pipe size to another.
- Reed Valve** Thin flat tempered steel plate fastened at one end.
- Reference Point** A specific known condition used for calibrating instruments.
- Reference Pressure** The pressure that data in a chart or table are based on.
- Reference Temperature** The temperature that the data in a chart or table are based on.
- Refractory** A material that can withstand very high temperature that is used to line the combustion chamber of furnaces.
- Refrigerant** Substance used in a refrigerating mechanism to absorb heat in an evaporator coil and to release its heat in a condenser.
- Refrigerant Blend** A mixture of two or more refrigerants that do not chemically combine.
- Refrigerant Charge** Quantity of refrigerant in a system.
- Refrigerant Control** Another name for the refrigerant expansion device or metering device in a refrigeration system.
- Refrigerant Quality** The percentage of liquid and vapor in a saturated mixture.
- Refrigerant Reclaim** (see Reclaim)
- Refrigerant Recovery** (see Recovery)
- Refrigerant Recycling** (see Recycling)
- Refrigerating Effect** The amount of heat in Btu/hr the system is capable of transferring.
- Refrigerant Expansion Device** Another name for the metering device or refrigerant control in a refrigeration system.
- Refrigerated Air Drier** Reduces the dew point of compressed air using a refrigeration system.
- Refrigeration** The process of transferring heat from one place to another.
- Refrigeration Cycle** A process during which a refrigerant absorbs heat at a relatively low temperature and reflects heat at a relatively higher temperature.
- Refrigeration Oil** Specially prepared oil used in refrigeration mechanism. It circulates with refrigerant.
- Refrigeration System** The combination of interconnecting devices, tubes, and/or pipes in which the refrigerant is circulated for the purpose of exchanging heat to produce cooling.
- Register** Combination grill and damper assembly on an air opening or at the end of an air duct.
- Regulator** A device that controls the flow through it to control the downstream pressure.
- Relative Humidity (RH)** The ratio of the weight of moisture that air actually contains at a certain temperature as compared to the amount that it could contain if it were saturated.
- Relay** Electrical mechanism that uses small current in the control circuit to operate a valve switch in the operating circuit.
- Relief Opening** The opening in a draft hood to permit ready escape to the atmosphere of flue products.
- Relief Valve** Safety device designed to open before a dangerous pressure is reached.

Reluctance The opposition to magnetic lines of force passing through a magnetic material.

Remote Bulb A temperature sensing element that works by pressure change that is transmitted through a capillary tube to the control. It is located in a different location from the component it controls.

Remote Condenser A condenser that is located by itself in a different location from the compressor.

Repulsion Start Induction Motor Type of motor that has an electrical winding on the rotor for starting purposes.

Resilient Motor Mount A motor mount that contains flexible material such as rubber to reduce transmission of vibration and noise.

Refrigerant Control Another name for the refrigerant expansion device or metering device in a refrigeration system.

Refrigerant Dye Used to locate difficult to find leaks in refrigeration systems. It actually dyes the refrigerant oil, not the refrigerant.

Refrigerant Management System An accounting system to document refrigerant use.

Resistance The opposition to current flow by a physical conductor.

Resistor An electronic component with a fixed electrical resistance that opposes current flow.

Resonance The pipe organ effect produced by a gas furnace when the frequency of the burner flame combustion and the pressure wave distance in the burner pouch are in exact synchronization.

Restrictor A refrigerant metering device with a small orifice that creates a pressure drop because of its restriction.

Retrofit, Mechanical Reworking existing equipment to meet current efficiency or code requirements.

Retrofit, Refrigerant Reworking an existing system to replace an older ozone depleting refrigerant with a newer environmentally friendly refrigerant.

Return Air Air returned from conditioned or refrigerated space.

Return Well The well that water from an open loop water source heat pump is returned to.

Return Piping That portion of the piping system that carries water from the terminal units back to the boiler.

Reverse Acting Control (RA) A switch controlled by temperature and designed to open on temperature drop and close on temperature rise.

Reverse Cycle Defrost A method of defrosting the evaporator by means of flow valve(s) to move hot vapor from the compressor into the evaporator.

Reverse Cycle Refrigeration System Commonly called a heat pump. A refrigeration system capable of reversing its operation and direction of heat transfer.

Reverse Return A two-pipe system in which the return connections from the terminal units into the return main are made in the reverse order from that in which the supply connections are made.

Reversing Valve A device used to change the direction of refrigerant vapor flow between the evaporator to compressor and from the compressor to the condenser depending on the heating or cooling effect desired.

Rheostat An adjustable or variable resistor.

Rich Mixture A mixture of gas and air containing too much fuel or too little air for complete combustion of the gas.

Riser A vertical pipe carrying gas or fluid up against gravity.

Rod and Tube Consists of a rod with a low expansion rate inside a tube with a high expansion rate. Thermal change produces linear movement for operating switches.

Rollout A condition where flame rolls out of a combustion chamber when the burner is turned on.

Roof Mounted The unit is mounted on a platform designed to distribute the weight of the unit over as wide an area of the roof as possible.

Root Mean Square Voltage (RMS) An accurate method of determining the effective voltage of an alternating current waveform.

Rotary Compressor Mechanism that compresses by trapping gas in a cylinder between an offset disc and one or more blades.

Rotating Blade Rotary Compressor A rotary compressor with blades housed in the offset disc that rotate with the compressor shaft.

Rotor Rotating part of a mechanism.

Run Capacitor A capacitor designed to stay in the circuit all the time in a permanent split capacitor motor.

Running Winding Electrical winding of motor that has current flowing through it during normal operation of the motor.

Runout This term generally applies to the horizontal portion of branch duct between the main trunk and the diffuser.

Rupture Disk A disk on a low pressure chiller that breaks to keep the pressure of the chiller from exceeding 15 psig.

S Lock An S shaped metal strip used to hold the long sides of rectangular metal duct together.

SI System The international system of units based on the metric system.

Saddle Valve Valve body shaped so it may be silver brazed to refrigerant tubing surface.

Safety Control Device that will stop the refrigerating unit if unsafe pressures and/or temperatures are reached.

Safety Interlock Switch A switch that prevents the operation of a machine at an unsafe condition, such as with a panel removed.

Safety Plug Device that will release the contents of a container above normal pressure conditions and before rupture pressures are reached.

Sail Switch A switch that detects airflow in ductwork using a "sail."

Satellite Compressor A compressor on a rack system that is dedicated to the lowest temperature and pressure evaporators.

Saturated Vapor A vapor condition that will result in condensation into droplets of liquid as vapor temperature is reduced.

Saturation Condition when both liquid and vapor are present or either phase is just about to appear or disappear.

Saybolt Universal Seconds (SUS, SSU) Used to measure oil viscosity. It is the time required for 60 ml of oil to flow through the calibrated orifice.

Scaling The formation of lime and other deposits on the water side surfaces of heat exchangers.

Schematic Wiring Diagram Another name for ladder or line diagram.

Schrader Valve Spring loaded device that permits fluid flow when a center pin is depressed.

Scotch Yoke Mechanism used to change reciprocating motion into rotary motion or vice versa.

Screw Compressor Compresses gas using two intermeshing, auger shaped screws turning in opposite directions.

Scroll Compressor Reduces the gas volume using a fixed and an orbiting scroll (spiral) to move gas from the outside of the scrolls to the inside.

Sealed Combustion Provides combustion air for a furnace, water heater, or boiler through a pipe, sealing off the combustion process from the air surrounding the equipment.

Seasonal Energy Efficiency Ratio (SEER) The total cooling of a central air conditioner in Btu during its normal annual usage period for cooling divided by the total electric input in watt-hours during the same period.

Seat The part of a valve body that the moveable portion of the valve rests against when sealing off.

Secondary Air Combustion air externally supplied to a burner flame at the point of combustion.

Secondary Refrigerant The water or brine that is circulated in a chiller system from the chiller to the heat load.

Secondary Refrigeration System Uses a primary refrigerant in a compression refrigeration system to cool a fluid that is circulated to the actual heat load. The secondary refrigerant uses all sensible cooling and does not change state.

Secondary Voltage The output, or load supply voltage, of a transformer.

Second Law of Thermodynamics Heat will flow only from material at a certain temperature to material at a lower temperature.

Seebeck Effect The generation of electrical current when a temperature difference exists between the two ends of a thermocouple.

Semiconductor A material that conducts electricity better than an insulator but not as well as a conductor.

Semihermetic Compressor A serviceable hermetic compressor.

Sensible Heat Heat energy added to or removed from a material that causes a change in temperature of the material without a change in state of the material.

Sensor A material or device that changes characteristics (electrical or mechanical) with a change in temperature and pressure.

Sequencer A control device used to control electrical circuits that use a heat motor for time delay of the operation of the device (see Heat Motor).

Series A circuit with one continuous path for current flow.

Series Wound Motor A brush-type motor with a wound armature that is wired in series with the field windings. It can operate on either DC or AC current.

Serviceable Hermetic Hermetic unit housing containing motor and compressor assembled by use of bolts or threads.

Service Factor (SF) A decimal factor that produces the maximum safe motor output when multiplied by the motor's nominal capacity rating.

Service Valve Device used by service technicians to check pressures and change refrigerating units.

Setpoint The temperature setting on a thermostat.

Shaded Pole Motor A small AC motor used for light start loads.

Shaft Seal A device used to prevent leakage between shaft and housing.

Shell and Coil Condenser A water cooled condenser consisting of a coil of tubing inside a shell. Water runs through the coil, and the refrigerant is in the shell.

Shell and Tube A water cooled condenser consisting of straight tubes passing through a shell. Water runs through the tubes, and the refrigerant is in the shell.

Short Circuit A low resistance connection (usually accidental and undesirable) between two parts of an electrical circuit.

Short Cycling Refrigerating system that starts and stops more frequently than it should.

Shroud A baffle around a propeller fan that separates the intake air from the exhaust air.

Sick Building Syndrome (SBS) A combination of ailments associated with an individual's exposure to a particular building.

Sight Glass Glass tube or glass window in refrigerating mechanism that shows the amount of refrigerant or oil in the system.

Silica Gel Chemical compound used as a drier that has ability to absorb moisture.

Silicon A semiconductor material used in the manufacture of electronic components.

Silver Brazing Brazing process in which brazing alloy contains some silver as part of the joining alloy.

Sine Wave The shape created when the voltage of an alternating current is graphed. It appears like a regular set of repeating peaks and valleys connected by a single smooth curve.

Single Package Heat Pump A system that has all components completely contained in one unit.

Single Phase An alternating current with a single sine waveform supplied by two wires.

Single-Phase Motor An electric motor designed to operate on single phase alternating current.

Single Phasing Occurs when a three phase motor is suddenly operating on a single phase of current instead of three because one of the three legs of power drops out. The current in the remaining two legs increases and the motor windings rapidly overheat.

Single Pipe System, Steam Heat A method of piping that allows a single pipe to carry both the steam to the radiators and the condensate back to the boiler.

Single Pipe System, Oil Heat Using a single pipe to carry the oil from the tank to the oil burner.

Single Pole Double Throw Switch (SPDT) A switch that can connect a center post to one of two circuits.

Single Pole Single Throw Switch (SPST) A switch that can open or close a single circuit.

Skin Condenser A condenser commonly found on chest type freezers that uses the outer surface of the cabinet to radiate heat.

Slinger Ring A ring around the outside of the condenser fan on window units that throws evaporator condensate water onto the condenser, causing the water to evaporate.

Sling Psychrometer Humidity measuring device with wet and dry bulb thermometers.

Slinky Loop A type of loop used in ground source heat pump installations in which a coil of tubing is stretched out in a ditch a flattened slinky.

Slip The difference between the synchronous speed and the actual speed of an induction motor.

Slug A quantity of liquid in the compressor clearance space that causes a hydraulic hammer.

Slugging A condition where liquid refrigerant is entering an operating compressor.

Smoke Test Test made to determine completeness of combustion.

Snap Action A means of ensuring positive closure of a mechanically operated electrical switch.

Snap-Disc A warped bimetal disc that snaps at a particular temperature to operate switches.

Soft Flame A flame partially deprived of primary air such that the combustion zone is extended and the inner cone is ill defined.

Solar Cell (see Photovoltaic Cell)

Solar Collector Typically, an insulated box that converts solar energy into thermal energy using a black surface.

Solar Heat Heat from visible and invisible energy waves from the sun.

Solder An alloy with a low melting temperature used for joining metals.

Soldering Joining two metals by adhesion of a low melting temperature metal (less than 840°F).

Solderless Terminals Wire terminals that connect to the wires using mechanical crimping rather than solder.

Solenoid A movable plunger activated by an electromagnetic coil.

Solenoid Valve Valve actuated by magnetic action by means of an electrically energized coil.

Solid The physical state of matter that has both a definite shape and volume.

Solid Fuel Combustible material such as wood, coal, or corn pellets.

Solubility The ability of one substance to be dissolved in another.

Solution, Chemical A liquid with another solid, liquid, or gas dissolved in it.

Solution, Refrigeration A mixture of absorbent and refrigerant in an absorption system.

Solution, Strong The solution leaving the absorber with a high percentage of refrigerant.

Solution, Weak The solution leaving the generator with a low percentage of refrigerant.

Sone A sound rating used for rating ventilation fans.

Soot A black substance, mostly consisting of small particles of carbon, that can result from incomplete combustion.

South Pole The pole on a magnet that magnetic lines of force flow into.

Space Heater A small heater designed to sit in the area that it heats.

Specific Gravity (SG) For a liquid or solid, the ratio of its density compared to water. For a vapor, the ratio of its density to air.

Specific Heat The amount of heat energy needed to change the temperature of a material at a given pressure as compared to an equal quantity of water or air at the same pressure.

Specific Volume The volume of a substance per unit mass; the reciprocal of density units; cubic feet per pound, cubic centimeters per gram, and so on.

Splash Lubrication Lubrication based on compressor components dipping into the oil in the crankcase.

Split Phase Motor Motor with two stator windings.

Split System Refrigeration or air conditioning installation that places condensing unit remote from evaporator.

Split System Heat Pump A heat pump with components located both inside and outside of a building—the most common type of heat pump installed in a home.

Spray Pond Used for cooling condenser water through evaporation by spraying water into the air.

Squirrel Cage Fan that has blades parallel to fan axis and moves air at right angle to fan axis.

Stack Switch A type of primary control and safety for oil furnaces that senses the temperature of the flue for operation.

Standard Air Air at standard conditions.

Standard Atmosphere Air at a pressure of 14.696 psia, 59°F, with a relative humidity of 30%.

Standard Conditions 68°F and 14.696 psia atmospheric pressure.

Standard Rating Conditions The conditions used for AHRI performance ratings. For cooling, 80°F dry bulb, 67°F wet bulb return air, and 95°F dry bulb outside air.

Standing Pilot A small flame that burns continuously that is used to light the main burners of a gas fired appliance.

Start Capacitor A capacitor that is used only during startup to increase the starting torque of a single phase motor.

Start Relay An electrical device that connects and/or disconnects the start winding of electric motor.

Starting Winding Winding in electric motor used for only the brief period when the motor is starting.

Starved Evaporator A term used to describe a condition where less refrigerant flows into the evaporator than is required for the heat load.

Static Condenser A natural draft condenser that depends more on radiation than convection for its cooling effect.

Static Electricity Electrical potential that results from the physical displacement of electrons from one object to another.

Static Head The amount of pressure difference a pump must overcome before it can move any water.

Static Pressure (P_s) The pressure exerted against the inside surfaces of a container or duct. Sometimes defined as burst pressure.

Stationary Blade Rotary Compressor A rotary compressor with a single blade housed in the compressor body that does not rotate with the compressor shaft.

Stator Stationary part of electric motor.

Steady State Condition The voltage and current levels of the controls on a gas furnace after ignition has been achieved and the indoor blower is operating.

Steam Jet Refrigeration Refrigerating system that uses a steam venturi to create high vacuum (low pressure) on a water container causing water to evaporate at low temperature.

Steam Water in a vapor state.

Steam Heating A heating system in which water absorbs heat in a boiler where it boils and gives off heat from radiators where it condenses.

Steam Trap A device that will prevent the flow of steam, but will allow the flow of condensate.

Step Motor A motor used for precisely positioning valves that moves in small repeatable steps.

Strainer A screen used to retain solid particles while liquid passes through.

Stratification Condition in which air lies in temperature layers.

Stratosphere The portion of the atmosphere approximately 12–30 mi above the earth. The ozone layer is in the stratosphere.

Stroke, Actuator The distance that an actuator for a damper or valve can move.

Stroke, Compressor The distance that a piston travels in the cylinder of a reciprocating compressor.

Subbase The mounting base for a low voltage thermostat where electrical connections are made.

Subcooled Liquid Liquid at a temperature lower than is possible when it is in equilibrium with its vapor. The pressure is higher than the vapor pressure.

Subcooling The reduction of the temperature of a liquid below its condensing temperature.

Subcritical A refrigeration process that take place below the refrigerant critical point.

Sublimation Condition where a substance changes from a solid to a gas without becoming a liquid.

Suction Line Tubing or pipe used to carry refrigerant vapor from the evaporator to the compressor in single function systems or from the reversing valve to the compressor in dual function systems.

Suction Line Accumulator (see Accumulator)

Suction Pressure Pressure in the low side of the refrigeration system. Also called low side pressure or suction pressure.

Suction Service Valve A two way manually operated valve located at the inlet to the compressor.

Suction Valves The valves on the underside of the valve plate of a reciprocating compressor that allow gas to enter the cylinder on the downstroke.

Sump A reservoir at the bottom of a piece of equipment that circulates water, such as a cooling tower.

Supercritical A refrigeration process that takes place above the refrigerant critical point.

Superheat Heat energy added to a gas so that the enthalpy is higher than for saturated vapor at the same pressure. The heat added to a vapor to raise the sensible temperature of the vapor above its boiling point.

Supplementary Heat The auxiliary heat provided at temperatures below the heat pump balance point. In most cases this is done with electric heating elements that are part of the heat pump system installation. A gas or oil furnace also can be used to provide supplementary heat when a heat pump is added to an existing fossil fuel heating system.

Surge Tank Container connected to a refrigerating system that increases gas volume and reduces the rate of pressure change.

Sustainability A building designed in such a way that can continue indefinitely into the future without damaging or depleting natural resources.

Swaging Enlarging a tube end so that another tube of the same size will fit inside it.

Swaging, Tool A tool for swaging tubing.

Swamp Cooler An air conditioner that uses water evaporation to reduce the temperature of the air.

Swash Plate Wobble plate. Device used to change rotary motion to reciprocating motion.

Sweating This term has two definitions in air conditioning or heat pump work: (1) formation of moisture on the outside of cold pipes or ducts; and (2) joining of two metals by the adhesive action of a third metal.

Sweet Water Tap water.

Synchronous Speed The theoretical speed that an alternating current induction motor would turn if the rotor turned at the same speed as the magnetic pulses in the motor windings.

Synthetic Not naturally occurring, manmade.

Synthetic Lubricant A synthetically derived chemical, such as polyol ester, that is used for lubrication.

Synthetic Dust Weight Arrestance A method of testing air cleaner efficiency using manufactured "dust" with its size carefully controlled.

System Charge The type and amount of refrigerant in a system, usually stated on the data plate.

System Lag Time delay between when a condition is sensed and when a system begins to act on the condition.

System Overshoot Space temperature exceeding the thermostat setpoint in a heating system.

Tankless Water Heater An indirect water heater designed to operate without a hot water storage tank.

Tap (Screw Thread) Tool used to cut internal threads.

Temperature Degree of hotness or coldness as measured by a thermometer.

Temperature Glide The temperature difference between the dew point and the bubble point of a zeotropic refrigerant.

Temperature-Humidity Index An index that combines air temperature and humidity to describe levels of comfort.

Temperature-Pressure Relationship (see Pressure-Temperature Relationship)

Temperature-Pressure Chart (TP Chart) (see Pressure-Temperature Chart)

Temperature-Pressure Relief Valve (TPR) A valve that opens to relieve the pressure on a closed water system if the pressure or temperature exceeds a safe level.

Temperature Sensing Bulb A bulb filled with a volatile fluid or gas with a capillary tube that transmits pressure from the bulb to the controlled device. Used with thermostatic expansion valves or thermostats.

Temperature Swing The difference between the low temperature and the high temperature in a controlled space.

Terminal Units Radiators, convectors, baseboard, unit heaters, finned tube, and so on.

Terminal Velocity The speed of the airstream leaving a diffuser when it has slowed to a point that it no longer effectively mixes with room air. Typically between 50–150 fpm.

Test Light An electrical test instrument that indicates the presence of voltage by illuminating a light.

Testing, Adjusting, and Balancing (TAB) Testing system performance and making adjustments in the system to make actual system operation match design specification. The term is often used to refer to airflow adjustments, but all aspects of system performance should be evaluated.

Testing, Adjusting and Balancing Bureau (TABB) An organization affiliated with the sheet metal industry that certifies TAB technicians.

Therm A unit of heat having a value of 100,000 Btu.

Thermal Conductivity The ability of a material to transmit heat.

Thermal Conductivity, Earth The rate at which heat energy flows through an earth material. Expressed in Btu/ft² of the material surface times the temperature difference per thickness in feet of the material.

Thermal Cutout An overcurrent protection device that contains a heater element that affects a bimetal element designed to open a circuit in the event of electrical current flow above the rated amount of the device.

Thermal Resistance The resistance a material offers to the transmission of heat.

Thermistor An electrical device that changes electrical resistance with a change in temperature of the device.

Thermocouple Device that generates electricity using the principle that if two dissimilar metals are welded together and the junction is heated, a voltage will develop across the open ends.

Thermodynamics The study of heat and heat flow.

Thermoelectric Refrigeration A refrigerator mechanism that depends on the Peltier effect.

Thermometer Device for measuring temperatures.

Thermopile A pilot generator.

Thermostat A control device that responds to surrounding air temperatures.

Thermostat, Outdoor Ambient A control used to limit the amount of auxiliary electric heat according to the outdoor ambient temperature to reduce electrical surge and cost.

Thermostat, Termination A thermostat mounted on the outdoor coil that interrupts the defrost mode when the temperature of the coil reaches the cutout setpoint of the control.

Thermostat Droop Maintaining temperature lower than the setpoint.

Thermostatic Control A device that controls the operation of equipment according to the temperature of the air surrounding the control.

Thermal Expansion Valve (see Thermostatic Expansion Valve)

Thermostatic Expansion Valve (TEV, TXV) A valve operated by temperature and pressure within the evaporator coil.

Thermostatic Valve Valve controlled by thermostatic elements.

Thermostatic Water Valve A water regulating valve controlled by temperature used on water cooled systems.

Three Phase An alternating current with three sine waveforms separated by 120°, supplied by three wires.

Three Phase Motor An electric motor designed to operate on three phase alternating current.

Three Way Valve, Control A valve that controls flow from one inlet to two outlets.

Three Way Valve, Manual A manual valve with three ports and two seats often used as a manual refrigeration service valve.

Throttling Expansion of gas through an orifice.

Throw The distance that air travels from an air diffuser or register before reaching terminal velocity.

Thrust Bearing A bearing designed to withstand force pushing against the bearing in parallel with the shaft. Vertical mount fans require thrust bearings.

Timed Off Control A timer that begins timing when the unit cycles off to ensure a minimum off cycle time before allowing the unit to restart.

Time Delay A delay between when a control is energized and when it acts.

Time Delay Fuse A fuse that can withstand momentary overload. Commonly used with motors.

Time Delay Relay A relay whose coil is energized for a time period before its contacts open or close.

Timers Mechanism used to control the time cycling of an electrical circuit.

Timer, Defrost A timer that operates at the same time as the refrigeration system. After a set period of operating time, the timer trips to initiate a defrost operation if the termination thermostat is closed.

Ton Refrigerating effect equal to the melting of one ton of ice in 24 hr.

Torque Turning or twisting force.

Torque, Full Load The maximum torque that a motor can provide at its rated output.

Torque, Stall The amount of torque that a motor produces when energized and mechanically locked. This is the highest torque that a motor can produce.

Torque, Starting The amount of torque a motor produces when starting, typically much higher than full load torque.

Torque Wrenches Wrenches that may be used to measure the torque applied.

Torr A non-SI unit of vacuum equal to 1/760 of standard atmospheric pressure. A perfect vacuum is 760 Torr.

Total Energy Management (TEM) An energy management strategy that looks at the total energy use of a building rather than concentrating on specific components or systems.

Total Equivalent Warming Impact (TEWI) An index of global warming that takes into account both the direct and indirect global warming impact of a refrigerant.

Total Heat The sum of sensible heat and latent heat, referred to as enthalpy.

Total Pressure (P_t) The sum of the static pressure and the velocity pressure at the point of measurement.

Toxicity The degree to which something is poisonous. Refrigerants that are harmful in concentrations of 400 ppm or less are listed as higher toxicity.

Transcritical A refrigeration system which has part of its processes operating above the refrigerant critical point and part of its processes operating below the refrigerant critical point.

Transducer A device that produces an electronic signal based on a physical property such as temperature or pressure.

Transformer A device designed to change voltage.

Transmission, Heat Heat loss or gain through building components.

Triple Point The temperature and pressure where a substance can exist as a solid, liquid, and gas simultaneously.

Troposphere The lowest portion of the atmosphere, close to the earth's surface.

True RMS Meter Uses frequent value sampling and the root mean square formula to determine alternating current values.

Tube in a Tube Coaxial A heat exchanger constructed of a tube inside a tube sealed off from each other. Usually liquid is in the inner tube and refrigerant is in the outer tube.

Tubing Used for conveying fluids. Tubing has a consistent outside diameter and relatively thin walls compared to pipe.

Turbulent Flow The movement of a liquid or vapor in a pipe in a constantly churning and mixing fashion.

Turndown The ratio of maximum to minimum input rates.

Twinning Installing and wiring two furnaces to operate simultaneously as one larger unit.

Two Pipe System A hot water heating system using one pipe to supply heated water to the terminal units, and a second pipe to return the water from the terminal units.

Two Position Control A control that is either on or off.

Two Stage Air Conditioner Can operate at two separate capacities to better match unit capacity to load.

Two Stage Compressor Can operate at two separate capacities to better match the compressor capacity to the load. Used in two stage air conditioners and heat pumps.

Two Stage Vacuum Pump Produces a lower pressure and deeper vacuum by having two vacuum pumps in series; the discharge of the low stage feeds the suction of the high stage.

Two Stage Furnace Has a low firing rate and a high firing rate that can better match furnace capacity to the load.

Two Stage Heat Pump Can operate at two separate capacities to better match unit capacity to load. Allows increased heating capacity without oversizing the air conditioning.

Two Temperature Valve Another name for evaporator pressure regulator.

Two Way Valve A valve with one inlet and one outlet that has two positions: opened and closed.

U Factor Unit of measure of thermal conductivity.

U Value Another name for U factor.

Ultrasonic Leak Detector Detects gas leaks in refrigeration systems by hearing the ultrasonic whistle of the gas escaping.

Ultraviolet (UV) Invisible radiation waves with frequencies shorter than wavelengths of visible light and longer than X-ray.

Ultraviolet A (UVA) Long wavelength ultraviolet light with wavelengths of 400–315 nm.

Ultraviolet B (UVB) Medium wavelength ultraviolet light with wavelengths of 315–280 nm.

Ultraviolet C (UVC) Short wavelength ultraviolet light with wavelengths of 280–100 nm.

Underwriters Laboratories (UL) Independent standards and testing laboratory for the examination and testing of devices.

Unit Heater A fan and motor, a heating element, and an enclosure hung from a ceiling or wall.

Unit Ventilator A terminal unit in which a fan is used to mechanically circulate air over the heating coil.

Universal Motor A series wound DC motor that can operate on either AC or DC current.

Unvented Space Heater A gas fired space heater that releases all the products of combustion into the space it is heating.

Universal Motor A series wound motor used for small electric appliances and power tools. Universal motors can operate on either AC or DC current.

Unloader Device that reduces the capacity of a compressor by preventing some cylinders from compressing.

Upflow Furnaces and air handlers with airflow that is up vertically, entering at the bottom of the unit and leaving at the top.

Urethane Foam Type of insulation that is foamed in between inner and outer walls of a display case.

U.S. Green Building Council (USGBC) A nonprofit organization committed to a prosperous and sustainable future through cost-efficient and energy-saving green buildings

U-Tube Manometer Measures pressure by the height of liquid column that it will support in a U-shaped tube. Low pressure manometers are filled with water; higher pressure manometers are filled with mercury.

V Belt Drive belt with a V-shaped cross section.

Vacuum Reduction in pressure below atmospheric.

Vacuum Gauge Measures the level of a deep vacuum, usually in microns.

Vacuum Pump A high efficiency vapor pump used for creating deep vacuum in refrigeration systems for testing and/or drying purposes.

Valve Device used for controlling fluid flow.

Valve, Check A valve that will permit fluid flow in only one direction. Sometimes called a one way valve.

Valve, Expansion A modulating refrigerant metering device.

Valve Plate Part of compressor located between the top of the compressor body and the head that contains the compressor valves.

Valve, Reversing A valve used to change the direction of refrigerant flow in a heat pump system. Because there are four pipe connections, it is also called a four way valve.

Valve Seat (see Seat)

Valve, Service A device used by service technicians to connect pressure gauges into the refrigeration system.

Valve, Slide The slide valve portion of the reversing valve that shifts the refrigerant flow.

Valve, Solenoid A flow control valve controlled by an electromagnetic coil actuating a plunger off its seat.

Valve, Suction (see Suction Valves)

Valve, TXV, Bi-Flow A thermostatic expansion valve that is designed to provide pressure reduction and refrigerant flow control in either direction.

Valve Stem Depressor The part on the end of a refrigeration hose that pushes in the valve core when connecting to a Schrader valve.

Vapor The gas form of a substance. It takes the shape and volume of its container.

Vapor Barrier Thin plastic or metal foil sheet used to prevent water vapor from penetrating insulating material.

Vapor Charge Bulb Also called gas charge or limited charge. A temperature sensing bulb that has a limited amount of liquid so that all the liquid will be vaporized at the upper end of the bulb's operating temperature range.

Vapor Line Found only in dual action heat pumps. It is the suction line in the cooling mode and the hot gas line in the heating mode.

Vapor Lock The restriction or blockage of flow in a liquid line due to the presence of vapor in the line.

Vapor, Saturated A vapor whose temperature has been reduced to the point of condensation but condensation has not started.

Vapor Pressure The pressure exerted by a vapor on its surroundings.

Vapor Refrigerant Charging Adding refrigerant to a system in gas form.

Vapor Refrigerant Recovery Removing refrigerant from a system in vapor form.

Vaporization Changing physical state from a liquid to a gas.

Variable Air Volume (VAV) A method of zone control that varies the volume of air to the zone depending upon the load.

Variable Frequency Drive (VFD) A control for an AC electric motor that changes the speed of the motor by varying the frequency of the current to the motor.

Variable Pitch Pulley Pulley that can be adjusted to provide different pulley ratios.

Variable Resistor A resistor whose value can be adjusted, typically between 0 Ω and its maximum value.

Variable-Speed Motor A motor whose speed can be adjusted to meet varying load requirements.

Velocimeter Instrument used to measure air velocities.

Velocity (v) Speed.

Velocity Pressure (P_v) The pressure exerted in the direction of flow.

Vent-Free A gas fired appliance that is designed to operate without a vent whose combustion products are released into the area it is in.

Vented Space Heater A gas fired space heater whose combustion products are vented through a flue to the outside.

Vent Gases Products of combustion.

Ventilation The introduction of outdoor air into a building by mechanical means.

Venturi A section in a pipe or a burner body that narrows down and then flares out again.

Vibrasorber A refrigeration component for reducing vibration in refrigerant piping consisting of a corrugated inner tube and a woven metal outer casing.

Viscosity Measure of a fluid's ability to flow. Typically measured in Saybolt universal seconds.

Volatile A fluid that evaporates readily.

Volt (V) The unit of electrical potential or pressure.

Voltage The potential difference between two points.

Voltage, Effective A measure of AC voltage that states its effect in a resistive circuit.

Voltage, RMS Root mean square voltage is used to calculate the effective AC voltage. The instantaneous voltage is measured many times each cycle. Each of these values are squared, the average of the squares is found, and finally the square root of the average is the effective voltage.

Voltage, Minimum The minimum supply voltage to a piece of equipment.

Voltage, Maximum The maximum supply voltage to a piece of equipment.

Voltage, Nominal The standard AHRI voltage rating for a piece of equipment.

Voltage, Peak The voltage at the peak of an AC sine waveform.

Voltage Relay One that functions at a predetermined voltage value.

Voltmeter A meter that reads voltage.

Volt Ohm Milliammeter (VOM) A meter that measures voltage, resistance (ohms), and milliamps.

Volumetric Efficiency Ratio of the actual performance of a compressor and calculated performance.

Walk-in Cooler Large commercial refrigerated room.

Wastewater System A water cooled refrigeration system that does not recirculate the condenser cooling water.

Water Box The water manifolding portion of a chiller or boiler.

Water Coil A heat transfer coil designed for water.

Water Column (wc) A unit of pressure comparing the height of water column it will support.

Water Cooled Condenser A heat exchanger that uses water to remove the heat from the high temperature compressor discharge vapor.

Water Cooled Condensing Unit A condensing unit (high side) that is cooled by the use of water.

Water Cooler An appliance that cools drinking water.

Water Hammer A pounding sound made by the sudden increase in static pressure in the pipes when flowing water is stopped suddenly by the closing of a valve.

Water Loop The piping and components in a closed circuit.

Water Regulating Valve A valve that regulates the water flow through a water cooled condenser in response to condenser pressure.

Water Tube Boiler A hot water boiler in which the water is circulated through the tubes and the hot gases from combustion of the fuel are circulated around the tubes.

Watt (W) A unit of electrical power.

Watt-Hour (Wh) Using electrical power at the rate of 1 W for a period of 1 hr.

Welded Hermetic Compressor A compressor with both the compressor and motor inside a welded shell.

Well Water Source, Closed Loop A system that removes water from the earth by means of a drilled well and returns it to the earth by means of a separate drilled well.

Well Water Source, Open Loop A system that removes water from the earth by means of a drilled or bored well and returns the water to the earth through a separate disposal system.

Wet Bulb Temperature (wbt) A temperature taken with a wet bulb thermometer.

Wet Bulb Depression The difference between the dry bulb and wet bulb temperatures.

Wet Bulb Thermometer A thermometer that uses a wet sac on the bulb to measure the evaporation rate of the air sample.

Wet Cell Battery A battery with a liquid electrolyte solution.

Wet Heat Heating system using hot water or steam.

Wind Chill Factor The reduction in perceived temperature because of wind.

Wind Effect The increase in evaporation rate due to air travel over a water surface.

Winding Thermostat A temperature sensor that opens if the motor winding temperature exceeds a safe level.

Windmilling Backward fan rotation caused by wind blowing through outdoor fans when they are off.

Window Unit An air conditioner designed to be installed in a window.

Wire Connectors Electrical terminals that are fastened to wires by soldering or crimping that facilitate wire connection to components.

Wobble Plate Compressor A compressor with pistons that are parallel to the crankshaft that uses an offset disc to create reciprocating motion.

Work The transfer of energy.

Work Hardening Metal becoming brittle as a result of being repeatedly flexed.

Wye Connected Motor A three phase motor whose windings are joined at the center to form a wye.

Wye Transformer A three phase transformer whose windings are joined at the center to form a wye.

Zeotropic A blend that changes in composition as it boils.

Zone That portion of a building that has its temperature controlled by a single thermostat.

Zone Control The controller that coordinates operation of the dampers or valves in a zone control system.

Zone Damper A damper that controls the airflow to a particular zone in a zoned system.

Zone Control System A control system that maintains the condition of separate zones within a building.

Zone Valve A valve that controls water flow to a zone in a zoned hydronic heating system.
